With the onset of sleep, activity in these brainstem nuclei decreases, and their axon terminals release less neurotransmitter. With the withdrawal of the depolarizing neurotransmitters, the resting potentials of the cells of the thalamus and cortex become more negative (hyperpolarized), and the cells are less sensitive to excitatory synaptic input. Their processing of information is inhibited, and consciousness is lost.

An interesting neural event happens as a result of the hyperpolarization with the onset of sleep: cells begin to fire action potentials in bursts. The synchronization of these bursts over broad areas of cerebral cortex results in the EEG slow-wave

pattern that characterizes deep non-REM sleep. Studies of neurons of the thalamus and cortex have shown that their hyperpolarization during non-REM sleep is due to increased opening of K^+ channels, and that bursting is due to Ca^{2+} channels whose inactivation gates close rapidly and require hyperpolarization to be reopened. We can therefore explain the EEG pattern of non-REM sleep in terms of the properties of neurons and ion channels.

At the transition from non-REM to REM sleep, dramatic changes occur. Some of the brainstem nuclei that were inactive during non-REM sleep become active again, causing a general depolarization of cortical neurons. Thus in REM sleep the synchronized bursts of firing cease, and the EEG resembles that of the awake brain. Because the resting potentials of the neurons return to near threshold levels, the cortex can process information, and vivid dreams occur.

So why don't we act out our dreams? During REM sleep the brain inhibits both afferent (sensory) and efferent (motor) pathways; we are paralyzed during REM sleep. Limb twitches and the jerky eye movements are motor signals breaking through the inhibition. The bizarre nature of dreams may be due to the lack of sensory feedback to the cortex from the body and the outside world. In other words, a functioning cortex is out of touch with reality. The function of muscle paralysis during REM sleep may be to prevent the acting out of dreams.

Knowing the cellular mechanisms of sleep has not yet led to an understanding of its function. Many questions remain. Why do we have two sleep states with very different neurophysiological characteristics? Why does non-REM sleep always occur first? Why do the two states cycle during the rest period? We know sleep is essential for life, but we don't know why. One set of hypotheses is that sleep is necessary for the maintenance and repair of neural connections and for the neural changes

WORKING WITHDATA:

Sleep and Learning

Original Paper

Walker, M. P., T. Brakefield, A. Morgan, J. A. Hobson, and R. Stickgold. 2002. Practice with sleep makes perfect: Sleep-dependent motor skill learning. *Neuron* 35: 205–211.

Analyze the Data

Does sleep enhance learning and memory? To answer this question, we need to specify the kind of learning and have an accurate means of measuring it. Walker and colleagues at Harvard Medical School investigated procedural (motor skill) memory through a simple task. Subjects used their nondominant hand to type the number sequence 4-1-3-2-4 on a computer keyboard as fast and accurately as they could for 30 seconds. The computer provided scores for speed and accuracy. Training consisted of 12 trials of 30 seconds each, with 30-second rests between trials. Retesting consisted of two similar sessions. Subjects were trained either at 10 A.M. or at 10 P.M. with the first retest after 12 hours and the second retest after 24 hours. Thus, one group had a sleep phase between the two retest events, while the other group had a sleep phase between the training and the first retest event. The results are shown in the bar graphs (right).

Another group of subjects was similarly trained at 10 P.M. and tested the next morning at 10 A.M. However, during their overnight sleep session their EEGs were recorded. Overnight improvement in motor skill scores was then correlated with the quantitative analysis of their sleep stages. The results are given in the table below (remember that most people cycle through 4–5 complete sleep cycles over the course of a night).

Group C			
Stage of sleep cycle	Percent of total time asleep (mean ± standard error)	Correlation with motor skill improvement (correlation coefficient <i>r</i>)	Significance (<i>p</i> value)
Stage 1	3.1 ± 0.68	0.41	0.17
Stage 2	52.1 ± 1.94	0.66	0.01
Stage 3 (slow-wave)	10.2 ± 85	–0.26	0.40
Stage 4 (slow-wave)	11.4 ± 1.51	–0.17	0.59
REM sleep	18.4 ± 2.05	–0.32	0.30

QUESTION 1

What would you conclude from these data about the role of sleep or wake in the consolidation of a procedural memory?

QUESTION 2

Based on the tabular data and the text descriptions of sleep stages, what feature of sleep seems to be most important for procedural memory consolidation?

Go to **BioPortal** for all **WORKING WITHDATA** exercises

involved in learning and memory—and possibly forgetting. These hypotheses are supported by many experiments showing that performance of a learned task or recall of declarative information on the day following training is impaired if sleep is prevented, and is best following a good night’s sleep.

Language abilities are localized in the left cerebral hemisphere

No aspect of brain function is as integrally related to human consciousness and intellect as language. Therefore brain mechanisms that underlie the acquisition and use of language are extremely interesting to neuroscientists. A curious observation about language ability is that it resides in one cerebral hemisphere—which in 97 percent of people is the left hemisphere.

This phenomenon is referred to as the **lateralization** of language functions.

Fascinating research on this subject was conducted by Roger Sperry and his colleagues at the California Institute of Technology. The two cerebral hemispheres are connected by a tract of white matter called the corpus callosum. In one severe form of epilepsy, bursts of action potentials causing seizures travel between hemispheres via the corpus callosum. Cutting the tract eliminates the problem, and patients function well following surgery. However, these “split-brain” subjects display interesting deficits in language ability.

After the surgery, if an object is shown in the right visual field and the left eye is closed (see Figure 47.11), the patient can describe it verbally and in writing. If the object is shown

in the left visual field and the right eye is closed, the patient cannot describe it either verbally or in writing, but can use his or her left hand to point to a picture of the object. Without the connecting tissue between the two hemispheres, knowledge or experience of the right hemisphere can no longer be expressed in language.

Individuals who have suffered damage to the left hemisphere frequently suffer from some form of **aphasia**, a deficit in the ability to use or understand words. Studies of such individuals have identified several language areas in the left hemisphere.

- **Broca's area**, located in the frontal lobe just in front of the primary motor cortex, is essential for speech. Damage to Broca's area results in halting, slow, poorly articulated speech or even complete loss of speech, but the patient can still read and understand language.
- **Wernicke's area**, located in the temporal lobe close to its border with the occipital lobe, is more involved with sensory than with motor aspects of language. Damage to Wernicke's area can cause a person to lose the ability to speak sensibly while retaining the abilities to form the sounds of normal speech and to imitate its cadence. Such a patient cannot understand spoken or written language.
- The **angular gyrus**, located near Wernicke's area, is believed to be essential for integrating spoken and written language.

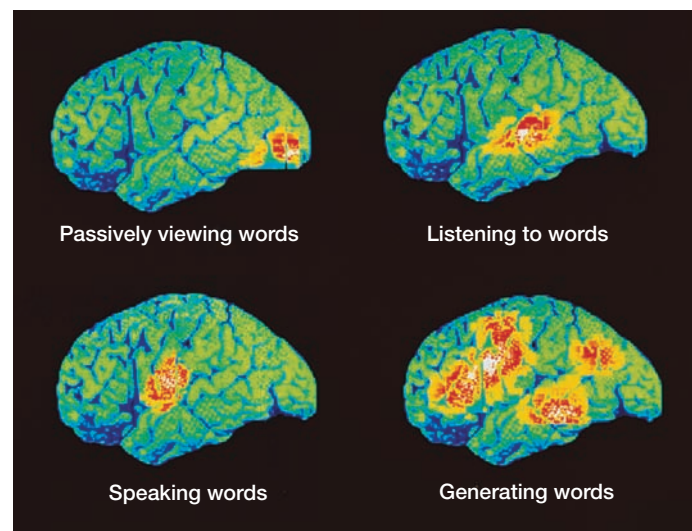

Normal language ability depends on the flow of information among various areas of the left cerebral cortex. Input from spoken language travels from the auditory cortex to Wernicke's area (**Figure 47.13A**). Input from written language travels from the visual cortex to the angular gyrus to Wernicke's area (**Figure 47.13B**). Commands to speak are formulated in Wernicke's area and travel to Broca's area and from there to the primary motor cortex. Damage to any one of those areas or the pathways between them can result in aphasia. Using modern methods of brain imaging, it is possible to see the metabolic activity in different brain areas when the brain is using language (**Figure 47.14**).

47.13 Language Areas of the Cortex Different regions of the left cerebral cortex participate in the processes of (A) repeating a word that is heard and (B) speaking a written word.

Some learning and memory can be localized to specific brain areas

Learning is the modification of behavior by experience. *Memory* is the ability of the nervous system to retain what is learned and experienced. Even very simple animals can learn and remember, but these two abilities are most highly developed in humans. Consider the amount of information associated with

47.14 Imaging Techniques Reveal Active Parts of the Brain

Positron emission tomography (PET) scanning reveals the brain regions activated by different aspects of language use. Radioactively labeled glucose is given to the subject. Brain areas take up radioactivity in proportion to their metabolic use of glucose. The PET scan visualizes levels of radioactivity in specific brain regions when a particular activity is performed. The red and white areas are the most active.

learning a language. The capacity of memory and the rate at which memories can be retrieved are remarkable features of the human nervous system.

LEARNING Learning that leads to long-term memory and modification of behavior must involve long-lasting synaptic changes. A phenomenon that may explain how long-term synaptic changes might arise is **long-term potentiation**, or **LTP**. LTP results from high-frequency electrical stimulation of certain identifiable circuits that makes these circuits more sensitive to subsequent stimulation. In contrast, continuous, repetitive, low-level stimulation of these same circuits reduces their responsiveness, a phenomenon that has been called **long-term depression** (**LTD**). LTP and LTD may be fundamental cellular or molecular mechanisms involved in learning and memory.

Several kinds of learning exist. A form that is widespread among animal species is **associative learning**, in which two unrelated stimuli become linked to the same response. The simplest example of associative learning was described by the Russian physiologist Ivan Pavlov. Pavlov observed that a dog salivates at the sight or smell of food. He then showed that if a non-food stimulus (such as a sound) was paired with the food, after a number of paired experiences the dog would salivate at the sound even if no food was present (see Figure 53.1). Pavlov called this a **conditioned reflex**.

More complex forms of learning, often referred to as “observational learning,” are the foundation of human intelligence. The general pattern of successful observational learning has three elements:

- We pay attention to another person’s behavior.
- We retain a memory of what we have observed.
- We try to copy or use that information.

A key to this scheme of learning is the way in which we create and recall memories.

MEMORY Some of the first insights into memory processes came from clinical treatment of patients with severe epilepsy, a disorder characterized by uncontrollable, local increases in neural activity. The resulting seizures can endanger these individuals. Serious cases of epilepsy are sometimes treated by destroying the part of the brain from which the surge of activity originates. To find the right area, the surgery is done under local anesthesia, with the patient remaining conscious. As different regions of the brain are electrically stimulated with electrodes, the patient reports the resulting sensations. Stimulation of some regions of the association cortex elicits recall of vivid memories. Such observations provided the first evidence that specific areas in the brain are associated with specific memories and that memory can be attributed to networks of neurons. Destroying a small area of the brain does not completely erase a memory, however, so it is postulated that memory is a function distributed over many brain regions and can be stimulated via many different routes.

You experience several forms of memory everyday. You have **immediate memory** for events that are happening now. Immediate memory is almost perfectly photographic but lasts only seconds. **Short-term memory** contains less information

but lasts longer—on the order of 10 to 15 minutes. When you are introduced to a group of several new people, you probably will have forgotten their names in an hour or so if you have not written them down, used them in a conversation, or made a conscious effort to repeat them. Repetition, use, or reinforcement by something that gets your attention (a title such as “President,” for example) facilitates the transfer of short-term memory to **long-term memory**, which can last for days, months, years, or a lifetime.

Knowledge about neural mechanisms for the transfer of short-term memory to long-term memory has come from observations of persons who have lost parts of the limbic system, notably the hippocampus. A famous case is that of the man identified as H.M., whose hippocampus on both sides of the brain was removed in 1953 in an effort to control severe epilepsy. After the surgery, H.M. was unable to transfer information to long-term memory. If someone was introduced to him, had a conversation with him, and then left the room for several minutes, when that person returned, H.M. did not recognize him—it was as if the conversation had never taken place. Up until his death 55 years later, H.M. remembered events that happened before his surgery but could not remember postsurgery events for more than 10 or 15 minutes.

Go to Media Clip 47.1

The Man with No Short-Term Memory

Life10e.com/mc47.1

Memory of people, places, events, and things is called **declarative memory** because you can consciously recall and describe them. **Procedural memory** cannot be consciously recalled and described; it is the memory of how to perform a motor task. When you learn to ride a bicycle, ski, or use a computer keyboard, you form procedural memories. Although H.M. was incapable of forming declarative memories, he could form procedural memories. When taught a motor task day after day, he could not recall the lessons of the previous day, yet his performance steadily improved. Thus procedural learning and memory must involve mechanisms different from those used in declarative learning and memory.

Memories can have considerable emotional content. As mentioned earlier, the limbic system plays a major role in controlling emotions. The amygdala, a component of the limbic system, is necessary for the emotion of fear and the formation of fear memories. Patients with a damaged amygdala do not associate fear reactions with their declarative memories. Memories can also have positive emotional content, and recalling those memories activates parts of the brain known to be associated with pleasurable sensations and reward, as revealed by brain imaging technologies.

We still cannot answer the question “What is consciousness?”

This chapter has only scratched the surface of the organization and functions of the human brain. Even with all of our knowledge of the human brain, and with all of the sophisticated new research tools, we still cannot answer the question “What is consciousness?”

The word “consciousness” is used in everyday language to refer to being awake in contrast to being asleep or in a coma. Here we are referring to the deeper meaning of being mentally aware of yourself, your environment, and events going on around you in such a way that you can plan for future events and make decisions based on experience, evidence, value systems, and predicted consequences. Speculations about consciousness have been the realm of philosophers, but we are getting closer to a neurobiological understanding.

The central requirement for conscious experience is a perception of self that can be integrated with information from the physical and social environment and information from past experience. The basis for a perception of self derives from the huge amount of somatosensory and visceral information that comes from all parts of the body. In the CNS of all vertebrates, this information is used for motor control and for homeostatic regulation. It enables animals to find food, seek mates, seek warmth, avoid cold, avoid danger, and so on. This afferent information goes to appropriate control and regulatory systems in the brainstem and forebrain.

In addition, some of this information goes to somatosensory areas of the cerebral cortex, so the animal is aware of certain information in the sense that it responds to it behaviorally. Visceral afferent information goes beyond its regulatory and control centers in the brainstem and hypothalamus to an area deep within the forebrain called the insular cortex, or **insula**. The insula appears to integrate physiological information from all over the body to create a sensation of how the body “feels.” Thus when an animal’s actions restore homeostasis, it “feels” better, and this is motivation to do the right thing for well-being.

In humans and the great apes, the insula is greatly expanded and has even acquired new types of spindle-shaped neurons not seen in other animals. The circuitry involving the insula has also evolved to communicate with parts of the brain that are involved in planning and decision making. In imaging studies, the insula is seen to be active in a great diversity of situations that involve strong feelings such as pleasure, disgust, humor, pain, lust, craving, humiliation, guilt, or empathy. Damage to

the insula causes apathy, loss of ability to enjoy music, loss of sexual response, and even loss of the ability to distinguish good food from spoiled food. Humans and the few other species that have expanded insulas and the new spindle cells are the only species that can recognize themselves in a mirror. Could it be that this very discrete part of our brains and its circuitry are the neurobiological bases for self-awareness and conscious experience?

RECAP 47.3

Even complex functions of the nervous system are beginning to be understood in terms of the properties of neurons and neural networks.

- What events in the brain are associated with wakefulness and the stages of sleep? **See p. 979**
- Why do some neurobiologists think that the insula might be involved in conscious experience? **See p. 983**

Does the firing pattern of hippocampal place cells during sleep represent a memory of recent experience that is being transferred into long-term memory?

ANSWER

Unfortunately we cannot give a rat an exam to ask what it remembers. However, we can look in other brain areas for electrophysiological patterns of activity that correlate with the hippocampal place cell patterns. Wilson and colleagues described the fast replay of the hippocampal place cell patterns as “ripples.” They observed that these ripples were tightly coupled to EEG brainwaves that spread to cortical areas of the brain. When they recorded in some of those other areas—the frontal cortex and the visual cortex—they found similar patterns of firing (i.e., ripples) in those areas that were synchronized to the hippocampal ripples. They hypothesized that the ripples did represent memory transcripts that were transferred to and stored in areas of the cortex.

47.1

How Is the Mammalian Nervous System Organized?

- The brain and spinal cord make up the **central nervous system (CNS)**; the cranial and spinal nerves make up the **peripheral nervous system (PNS)**.
- The nervous system can be modeled conceptually in terms of the direction of information flow and whether we are conscious of the information. The afferent component carries information from the PNS to the CNS, and the efferent component directs information from the CNS to the peripheral parts of the body. **Review Figure 47.1**
- The vertebrate nervous system develops from a hollow dorsal neural tube. The brain forms from three swellings at the anterior end of the neural tube, which become the **hindbrain**, the **midbrain**, and the **forebrain**. The forebrain develops into the

cerebral hemispheres (the **telencephalon**, or **cerebrum**) and the underlying thalamus and hypothalamus (which together compose the **diencephalon**). The midbrain and hindbrain develop into the **brainstem** and the **cerebellum**. **Review Figure 47.2**

- The spinal cord communicates information between the brain and the rest of the body.
- The **reticular activating system** is a complex network that directs incoming information to appropriate brainstem **nuclei** that control autonomic functions, and transmits the information to the forebrain that results in conscious sensation. The reticular activating system controls the level of arousal of the nervous system, including sleep and wakefulness.
- The **limbic system** is an evolutionarily primitive part of the telencephalon that is involved in emotions, physiological drives (such as hunger and thirst), instincts, and memory. **Review Figure 47.3**

continued

CHAPTER SUMMARY 47

- The cerebral hemispheres are the dominant structures of the human brain. Their surfaces are layers of neurons called the **cerebral cortex**. The cerebral hemispheres can be divided into the **temporal, frontal, parietal, and occipital lobes**. Many motor functions are localized in parts of the frontal lobe. Information from many sensory receptors projects to a region of the parietal lobe. Visual information projects to the occipital lobe, and auditory information projects to a region of the temporal lobe. **Review Figures 47.4, 47.5, 47.6, ACTIVITY 47.1**

47.2 How Is Information Processed by Neural Networks?

- The **autonomic nervous system (ANS)** consists of efferent pathways that control the physiological function of organs and organ systems. Its **sympathetic** and **parasympathetic** divisions are characterized by their anatomy, neurotransmitters, and effects on target tissues. **Review Figure 47.9**
- The neural network of vision involves patterns of light falling on **receptive fields** in the retina. Receptive fields have a center and a surround, which have opposing effects on ganglion cell firing. **Review Figure 47.10, ANIMATED TUTORIALS 47.1, 47.2**
- Information from retinal ganglion cells is communicated via the optic nerve to the thalamus and then to the visual cortex. The visual cortex seems to assemble an image of the visual world by analyzing edges of patterns of light.
- **Binocular vision** is possible because information from both eyes is communicated to binocular cells in the visual cortex. These cells interpret distance by measuring the disparity between where the same stimulus falls on the two retinas. **Review Figure 47.11**

47.3 Can Higher Functions Be Understood in Cellular Terms?

- Humans have a daily cycle of sleep and waking. Sleep can be divided into **rapid eye movement (REM) sleep** and non-REM sleep. Deep non-REM sleep is known as **slow-wave sleep** because of its characteristic EEG patterns. **Review Figure 47.12**
- Language abilities are localized mostly in the left cerebral hemisphere, a phenomenon known as **lateralization**. Different areas of the left hemisphere—including **Broca's area**, **Wernicke's area**, and the **angular gyrus**—are responsible for different aspects of language. **Review Figures 47.13, 47.14, ACTIVITY 47.2**
- Some learning and memory processes have been localized to specific brain areas. Long-lasting changes in synaptic properties referred to as long-term potentiation (LTP) and **long-term depression (LDP)** may be involved in learning and memory.
- Complex memories can be elicited by stimulating small regions of association cortex. Damage to the hippocampus can destroy the ability to form long-term **declarative memory** but not **procedural memory**.
- A sense of the physiological state of the body may be created in the **insula** of the cortex from visceral afferent information. Evolution of this integrative function in higher primates and humans could be the basis for conscious experience.

See **ACTIVITY 47.3** for a concept review of this chapter

CHAPTERREVIEW

REMEMBERING

- Which statement about the limbic system is *not* true?
 - Damage to one structure in the limbic system makes it impossible to form a fear memory.
 - The limbic system is involved in basic physiological drives, instincts, and emotions.
 - The limbic system consists of primitive forebrain structures.
 - The limbic system contains nuclei that maintain the cortex in an awake state.
 - In humans, a part of the limbic system is necessary for the transfer of short-term memory to long-term memory.
- Which of the following represents the largest portion of the human cerebral cortex?
 - The frontal lobes
 - The primary somatosensory cortex
 - The temporal cortex
 - The association cortex
 - The occipital cortex
- Which statement about the autonomic nervous system is true?
 - The sympathetic division is afferent, and the parasympathetic division is efferent.
 - The transmitter norepinephrine is always excitatory, and acetylcholine is always inhibitory.
 - Each pathway in the autonomic nervous system includes two neurons, and the neurotransmitter of the first neuron is acetylcholine.
 - The cell bodies of many sympathetic preganglionic neurons are in the brainstem.
 - The cell bodies of most parasympathetic postganglionic neurons are in or near the thoracic and lumbar spinal cord.
- Which statement is *not* true about some cells in the visual cortex?
 - They receive input from only the left visual field.
 - They respond most strongly to bars of light falling at specific locations on the retina.
 - They receive inputs directly from single retinal ganglion cells.
 - They receive input from both eyes.
 - They respond most strongly to an object when it is a certain distance from the eyes.

5. Which of the following conclusions was supported by experiments on split-brain patients?
 - a. Language abilities are localized mostly in the left cerebral hemisphere.
 - b. Language abilities require both Wernicke's area and Broca's area.
 - c. The ability to speak depends on Broca's area.
 - d. The ability to read depends on Wernicke's area.
 - e. The left hand is served by the left cerebral hemisphere.

UNDERSTANDING & APPLYING

6. A person receives a stab wound to the left side of his neck. Miraculously, blood vessels are spared. Afterward, however, the man's left pupil remains more constricted than his right pupil, and he drools out of the left side of his mouth. How can you explain these symptoms?
7. The eyes of some animals point in the same direction as do those of humans, but in other animals (such as birds) the eyes are positioned more laterally so they point in different directions. What would be the selective advantages of these different anatomical arrangements, and what kinds of animals would you expect to have one or the other?
8. Sleepwalking occurs in up to 15 percent of the population, although it is more common in children. While sleepwalking, individuals engage in mostly routine activities but are unaware of their actions when they awake. In what state of sleep do you think sleepwalking occurs, and why?

ANALYZING & EVALUATING

9. Patient X received a gunshot wound that destroyed the right side of his spinal cord at the midthoracic level. He has no conscious motor control over his right leg, but that leg is sensitive to painful stimuli, although not to touch. His right leg shows a reflex response when a painful stimulus is applied to his left foot, but he does not sense that stimulus as pain in his left foot. Considering that different types of information flow in different tracts in the spinal cord and that some types of information cross from one side of the cord to the other, what do the symptoms of this patient tell you about the routes of motor commands, pain sensory information, and mechanosensory information in the spinal cord?
10. High-density EEG recordings are made from arrays of 128 or 256 electrodes evenly spaced over the head. This allows measurements of local changes in EEG activity. When a person was trained in a task to use his left hand to do a difficult motor task, during subsequent sleep the slow-wave activity recorded over the posterior region of his right frontal cortex was greater than that recorded on the opposite side of his brain. Explain these results both in terms of neuroanatomy and possible functions of sleep.

CHAPTER OUTLINE

- 48.1** How Do Muscles Contract?
- 48.2** What Determines Skeletal Muscle Performance?
- 48.3** How Do Skeletal Systems and Muscles Work Together?

THE OLYMPIC RECORD for the women's long jump is 7.4 meters, set in 1988 by Jackie Joyner-Kersey. Another world-record long jump that still stands was set two years earlier by Rosie the Ribeter, who jumped 6.5 meters. Rosie was a frog competing in the Calaveras County Jumping Frog Contest. In some ways Rosie's jump is more impressive. While Jackie's jump was about 5 times her body length (i.e., her height), Rosie's was about 20 times her body length.

Both jumps were powered by skeletal muscle. Muscle tissue responds to commands from the nervous system. The cellular mechanisms of muscle contraction are essentially the same in the frog and the human, so why is the frog's jump so much more impressive? The answer involves the concept of *leverage*, which depends on the muscles and skeletal elements working together.

Both frog and human jumping muscles pull on bones that are connected at joints to make levers. A lever makes it possible for the same force to move a large mass a small distance or a small mass a large distance. The ratio of a frog's leg length to its body mass is simply greater than that in a human. Thus the frog's legs are better at moving a small mass a long distance than are the human's legs.

Let's add a flea to our interspecies competition. The flea can jump more than 200 times its body length. This incredible performance is not due to feats of leverage, because no muscle can contract fast enough to explain the take-off velocity of the flea. A different mechanism evolved in the flea—a kind of slingshot action. At the base of the flea's jumping legs is an elastic material that is compressed by muscles while the flea is resting.

Champion Jumpers Relative to their size, many animals have more impressive jumping skills than humans. This leopard frog (*Rana pipiens*) can leap distances up to 20 times its body length.

When a trigger mechanism is released, the elastic material recoils and “fires” the flea into the air.

In a contest of jumping efficiency, the uncontested champion would be the kangaroo. As a human runs faster, the number of strides and the energy expended per minute increase rapidly. Neither is true for the kangaroo. When moving at speeds from about 5 to 25 kilometers per hour, the kangaroo takes the same number of strides per minute and its metabolic rate *does not increase*.

The ability to move about in the environment is a distinguishing feature of most animals. Muscles and skeletons—musculoskeletal systems—enable animals to move.

How can the kangaroo increase its speed fivefold without increasing its metabolic expenditure?

See answer on p. 1003.

Go to Activity 48.1
The Structure of a Sarcomere
Life10e.com/ac48.1

48.1

How Do Muscles Contract?

Most behavior and many physiological actions, such as beating of the heart and moving of food through the digestive tract, depend on muscle contraction. Wherever tissues contract, muscle cells are responsible. As introduced in Section 40.2 and shown in Figure 40.4, there are three types of vertebrate muscle:

- **Skeletal muscle** is responsible for all voluntary movements, such as running or playing a piano. It is also involved in many involuntary actions, such as breathing, shivering, and maintaining posture.
- **Cardiac muscle** is responsible for the beating of the heart.
- **Smooth muscle** creates movement in many hollow internal organs, such as the digestive system, bladder, and blood vessels, and is under the control of the autonomic (involuntary) nervous system.

All three muscle types use the same sliding filament contractile mechanism, and we will begin our study of musculoskeletal movement by describing its underlying molecular mechanisms. We will use vertebrate skeletal muscle as our primary example. Later we will discuss the differences in cardiac and smooth muscle that adapt them to their particular functions.

Sliding filaments cause skeletal muscle to contract

Skeletal muscle is also called striated muscle because of its striped appearance (Figure 48.1; also see Figure 40.4A). Skeletal muscle cells, called **muscle fibers**, are large and have many

48.1 The Structure of Skeletal Muscle A skeletal muscle is made up of bundles of muscle fibers. Each muscle fiber is a multinucleate cell containing numerous myofibrils, which are highly ordered assemblages of thick myosin and thin actin filaments. The arrangement of the actin and myosin filaments gives skeletal muscle fibers their characteristic striated appearance.

48.2 Sliding Filaments

The banding pattern of the sarcomere changes as it shortens. Observations of electron micrographs such as those on the right led to the sliding filament model of muscle contraction.

nuclei. These multinucleate cells form in development through the fusion of many individual embryonic muscle cells called myoblasts. A specific muscle such as your biceps (which bends your arm) is composed of hundreds or thousands of muscle fibers bundled together by connective tissue.

Muscle contraction is due to the interaction between the contractile proteins **actin** and **myosin**. Within muscle cells, actin and myosin molecules are organized into filaments. Actin filaments are also called thin filaments, and myosin filaments are thick filaments. The two kinds of filaments lie parallel to each other. When muscle contraction is triggered, the actin and myosin filaments slide past each other in a telescoping fashion.

What is the relationship between a skeletal muscle fiber and the actin and myosin filaments responsible for its contraction? Each muscle fiber (cell) is packed with **myofibrils**—bundles of thin actin and thick myosin filaments arranged in orderly fashion. In most regions of the myofibril, each thick myosin filament is surrounded by six thin actin filaments, and each thin actin filament sits within a triangle of three thick myosin filaments.

A longitudinal view of a myofibril reveals why skeletal muscle appears striated. The myofibril consists of repeating units called **sarcomeres**. Each sarcomere is made of overlapping filaments of actin and myosin, which create a distinct banding pattern (see Figure 48.1). Before the molecular nature of the muscle banding pattern was known, the bands were given names that are still used today. Each sarcomere is bounded by Z lines, which anchor the thin actin filaments. Centered in the sarcomere is the A band, which contains all the myosin filaments. The H zone and the I band, which appear light, are regions where actin and myosin filaments do not overlap in the relaxed muscle. The dark stripe within the H zone is called the M band; it contains proteins that hold the myosin filaments in their regular arrangement.

The bundles of myosin filaments are held in a centered position within the sarcomere by a protein called **titin**. Titin is the largest protein in the body; it runs the full length of the sarcomere from Z line to Z line. Each titin molecule runs right

through a myosin bundle. Between the ends of the myosin bundles and the Z lines, titin molecules are very stretchable, like bungee cords. In a relaxed skeletal muscle, resistance to stretch is mostly due to the elasticity of the titin molecules.

As the muscle contracts, the sarcomeres shorten and the band pattern changes. The H zone and the I band become much narrower, and the Z lines move toward the A band as if the actin filaments were sliding into the H zone, the region occupied by the myosin filaments (Figure 48.2). In the mid 1950s this observation independently led two teams of British biologists to propose the **sliding filament model** of muscle contraction.

It is not uncommon in science for critical breakthroughs to be made simultaneously in different laboratories, but in this case the coincidences are remarkable. The leaders of the two teams were named Hugh Huxley and Andrew Huxley—but they were not related. Working in separate Cambridge University labs, the two groups proposed the sliding filament model at the same time, and both papers were published in the same issue of the journal *Nature*.

Actin–myosin interactions cause filaments to slide

To understand how the sliding filament model explains muscle contraction, we must first examine the structures of actin and myosin (Figure 48.3). A myosin molecule consists of two long polypeptide chains coiled together, each ending in a large globular head. A myosin filament is made up of many myosin molecules arranged in parallel, with their heads projecting sideways at each end of the filament.

An actin filament consists of actin monomers polymerized into a long molecule that looks like two strands of pearls twisted together. Twisting around the actin chains is another protein, **tropomyosin**, and attached to tropomyosin at intervals are molecules of **troponin**. We'll discuss the latter two proteins in more detail later in this section.

The myosin heads can bind specific sites on actin, to form cross-bridges between the myosin and the actin filaments. Moreover, when a myosin head binds to an actin filament, the head's conformation changes. As the head bends, it exerts a

48.3 Actin and Myosin Filaments Overlap to Form Myofibrils

Myosin filaments are bundles of molecules with globular heads and polypeptide tails; the protein titin holds these filaments centered within the sarcomeres. Actin filaments consist of two chains of actin monomers twisted together. They are wrapped by chains of the polypeptide tropomyosin and are studded at intervals with another protein, troponin.

tiny force that causes the actin filament to move 5 to 10 nanometers relative to the myosin filament. When the myosin heads are bound to actin, they can bind and hydrolyze ATP. The energy released when this happens changes the conformation of the myosin head, causing it to release the actin and return to its extended position, from which it can bind to actin again.

Together these details help to explain the cycle of events that cause the actin and myosin filaments to slide past each other and shorten the sarcomere. They also explain rigor mortis—the stiffening of muscles soon after death. ATP binding causes myosin to release from actin, so when ATP production stops with death, myosin cannot release and the muscles stay contracted. Eventually, however, the proteins lose their integrity and the muscles soften. The timing of these events helps a medical examiner estimate the time of death.

We have been discussing the cycle of contraction in terms of a single myosin head. Remember that each myosin filament has many myosin heads at both ends and is surrounded by six actin filaments; thus the contraction of the sarcomere involves a great many cycles of interaction between actin and myosin molecules. That is why when a single myosin head breaks its contact with actin, the actin filaments do not slip backward.

Actin–myosin interactions are controlled by calcium ions

Like neurons, muscle cells are excitable—that is, their plasma membranes can generate and conduct action potentials. In skeletal muscle fibers, action potentials are initiated by motor neurons arriving at a **neuromuscular junction**. The axon terminals of motor neurons are generally highly branched and form synapses with hundreds of muscle fibers (**Figure 48.4**). A motor neuron and all of the fibers with which it forms synapses constitute a **motor unit**. The fibers contract simultaneously when the unit's motor neuron fires. A muscle can consist of many motor units. Thus there are two ways to increase a muscle's strength of contraction—increase the firing rate of an individual motor neuron, or recruit more motor neurons.

Molecular Mechanisms of Muscle Contraction

Life10e.com/at48.1

When an action potential arrives at a neuromuscular junction, the neurotransmitter acetylcholine is released from the motor neuron terminals, diffuses across the synaptic cleft, binds to receptors in the postsynaptic membrane, and causes ion channels in the motor end plate to open (see Figures 45.13 and 45.14). Most of the ions that flow through these channels are Na^+ , and therefore the motor end plate is depolarized. The depolarization spreads to the surrounding plasma membrane of the muscle fiber, which contains voltage-gated sodium channels. When threshold is reached, the plasma membrane fires an action potential that is conducted rapidly to all points on the surface of the muscle fiber.

An action potential in a muscle fiber also travels deep within the cell. The plasma membrane is continuous with a system of tubules that descend into the muscle fiber cytoplasm (also called the **sarcoplasm**). The action potential that spreads over the plasma membrane also spreads through this system of transverse tubules, or **T tubules** (**Figure 48.5**).

The T tubules come very close to the endoplasmic reticulum (ER) of the muscle cell. In muscle cells the ER is called the **sarcoplasmic reticulum**, and it is a closed compartment surrounding every myofibril. Calcium pumps in the sarcoplasmic reticulum

48.4 The Neuromuscular Junction Axons branching from a single motor neuron end in terminals that innervate multiple skeletal muscle fibers.

48.5 T Tubules Spread Action Potentials into the Fiber

An action potential at the neuromuscular junction spreads throughout the muscle fiber via a network of T tubules, triggering the release of Ca^{2+} from the sarcoplasmic reticulum.

Life10e.com/ac48.2

take up Ca^{2+} from the sarcoplasm. Therefore when the muscle fiber is at rest, there is a high concentration of Ca^{2+} in the sarcoplasmic reticulum and a very low concentration of Ca^{2+} in the sarcoplasm.

Spanning the space between the membranes of the T tubules and the membranes of the sarcoplasmic reticulum are two proteins. One protein, the dihydropyridine (DHP) receptor, is located in the T tubule membrane; it is voltage-sensitive and changes its conformation in response to an action potential. The other protein, the ryanodine receptor, is located in the sarcoplasmic reticulum membrane and is a Ca^{2+} channel. These two proteins are physically connected. When the DHP receptor is activated by an action potential, it changes conformation; this allows Ca^{2+} to flow through the ryanodine receptor from the sarcoplasmic reticulum to the sarcoplasm. Ca^{2+} ions diffusing through the sarcoplasm surrounding the actin and myosin filaments trigger the interaction of actin and myosin and the sliding of the filaments. How do the Ca^{2+} ions do this?

An actin filament, as we have seen, is a helical arrangement of actin monomers. Twisted around the actin filament are two strands of the protein tropomyosin (Figure 48.6; see also Figure 48.3). At regular intervals, the filament also includes a globular protein, troponin. The troponin molecule has three subunits: one binds actin, one binds tropomyosin, and one binds Ca^{2+} .

When the muscle is at rest, the tropomyosin strands are positioned so that they block the sites on the actin filament where

3 ...which causes a change in the conformation of the DHP receptor and ryanodine receptor, releasing Ca^{2+} stored in the sarcoplasmic reticulum.

4 Released Ca^{2+} diffuses in sarcoplasm, stimulating muscle contraction.

5 Ca^{2+} is taken up by the sarcoplasmic reticulum, terminating muscle contraction.

myosin heads can bind. When Ca^{2+} is released into the sarcoplasm, it binds to troponin, changing its conformation. Because the troponin is bound to the tropomyosin, this conformational change twists the tropomyosin enough to expose the actin-myosin binding sites. Thus the cycle of making and breaking actin-myosin bonds is initiated, the filaments are pulled past each other, and the muscle fiber contracts. When the calcium pumps in the sarcoplasmic reticulum membranes remove the Ca^{2+} ions from the sarcoplasm, the conformation of the tropomyosin returns to the state in which it blocks the binding of myosin heads to actin, and the muscle fiber returns to its resting condition. Figure 48.6 summarizes this cycle.

48.6 Release of Ca^{2+} from the Sarcoplasmic Reticulum Triggers Muscle Contraction When Ca^{2+} binds to troponin, it exposes myosin-binding sites on the actin. As long as binding sites and ATP are available, the cycle of actin and myosin interactions continues and the filaments slide past each other.

Cardiac muscle is similar to and different from skeletal muscle

Like skeletal muscle, cardiac muscle appears striated because of the regular arrangement of actin and myosin filaments into sarcomeres (Figure 48.7). The difference between cardiac and skeletal muscle is that cardiac muscle cells are much smaller and have only one nucleus each (uninucleate). Cardiac muscle cells branch, and the branches of adjoining cells interdigitate into a meshwork that is resistant to tearing. As a result, the heart walls can withstand high pressures while pumping blood, without the danger of developing leaks. Adding to the strength of cardiac muscle are intercalated discs that provide strong mechanical adhesions between adjacent cells. Gap junctions are an important feature of cardiac muscle. These structures in the intercalated discs allow cytoplasmic continuity between cells (see Figure 7.19A). Because of gap junctions, cardiac muscle cells are electrically coupled. An action potential initiated at one point in a sheet of cardiac muscle spreads rapidly, causing a large number of cardiac muscle cells to contract simultaneously.

Certain cardiac muscle cells are specialized for generating and conducting electric signals. These pacemaker and conducting cells have a low density of actin and myosin filaments, but they initiate and coordinate the rhythmic contractions of the

48.7 Cardiac Muscle Cells Form a Strong Meshwork Cardiac muscle cells branch and interdigitate, forming a tear-resistant mesh that can withstand the pressure of blood pumping through the heart.

INVESTIGATING LIFE

48.8 Neurotransmitters Alter the Membrane Potential of Smooth Muscle Cells Earlier experiments showed that stretching the smooth muscles of the gut (as in the stretch applied by a full stomach) depolarizes the membranes, causing action potentials

that activate the contractile mechanism. This follow-up experiment showed that the parasympathetic neurotransmitter acetylcholine and the sympathetic neurotransmitter norepinephrine act antagonistically to alter the membrane potential of smooth muscle.^a

HYPOTHESIS Stimulation from neurotransmitters of the autonomic nervous system (ANS) induce contractions in the smooth muscles of the gut.

Method**Results**

CONCLUSION ANS neurotransmitters can alter membrane resting potentials and affect the rate at which smooth muscle cells fire action potentials, thus controlling smooth muscle contraction.

^aBolton, T. B. et al. 1999. *Annual Review of Physiology* 61: 85–115.

heart. (The molecular basis for this pacemaking function will be covered in Section 50.3.) Pacemaker cells make the vertebrate heartbeat myogenic, meaning it is generated by the heart muscle itself. A heart removed from a vertebrate can continue to beat with no input from the nervous system. Although input from the autonomic nervous system modifies the *rate* of the pacemaker cells, it is not essential for their continued rhythmic function.

The mechanism of excitation–contraction coupling in cardiac muscle cells is different from that in skeletal muscle cells. The T

tubules are larger, and the voltage-sensitive DHP receptor proteins in the T tubules are Ca^{2+} channels. These T tubule proteins are not physically connected with the ryanodine receptors in the sarcoplasmic reticulum. Instead, the ryanodine receptors are ion-gated Ca^{2+} channels. When an action potential spreads down the T tubules, it causes the voltage-gated channels to open, allowing extracellular Ca^{2+} to flow into the sarcoplasm. Increased sarcoplasmic Ca^{2+} concentration results in Ca^{2+} binding to the ryanodine receptors and opens calcium channels in the

sarcoplasmic reticulum. The resulting huge rise in sarcoplasmic Ca^{2+} concentration stimulates fiber contraction. This mechanism is called Ca^{2+} -induced Ca^{2+} release.

Smooth muscle causes slow contractions of many internal organs

Smooth muscle provides the contractile force for most of our internal organs, which are under the control of the autonomic nervous system. Smooth muscle moves food through the digestive tract, controls the flow of blood through blood vessels, and empties the urinary bladder. Structurally, smooth muscle cells are the simplest muscle cells. They are smaller than skeletal muscle cells, usually long and spindle-shaped, and each has a single nucleus. They are “smooth” because the actin and myosin filaments are not as regularly arranged as they are in skeletal and cardiac muscle, and so do not produce the striated appearance.

Some smooth muscle tissue, such as that from the wall of the digestive tract, has interesting properties. The cells are arranged in sheets, and individual cells in a sheet are in electrical contact with one another through gap junctions, as they are in cardiac muscle. As a result, an action potential generated in the membrane of one smooth muscle cell can spread to all the cells in the sheet of tissue. Thus the cells in the sheet contract in a coordinated fashion.

The plasma membranes of smooth muscle cells are sensitive to stretch, with important consequences. If the wall of the digestive tract is stretched in one location (as by a mouthful of food passing down the esophagus to the stomach), the membranes of the stretched cells depolarize, reach threshold, and fire action potentials, which cause the cells to contract. Thus smooth muscle contracts after being stretched, and the harder it is stretched, the stronger it contracts. This behavior of smooth muscle is important for moving food through the digestive system.

The walls of blood vessels are mostly smooth muscle. This is especially true on the arterial side where the blood is under higher pressure. Changes in vascular smooth muscle tone are responsible for controlling the distribution of blood in the body.

The neural influences on smooth muscle come from the two divisions of the autonomic nervous system. The neurotransmitters of the sympathetic and parasympathetic postganglionic cells alter the membrane potential of smooth muscle cells. For example, in the digestive tract, acetylcholine causes smooth muscle cells

to depolarize, making them more likely to fire action potentials and contract. Antagonistically, norepinephrine causes these muscle cells to hyperpolarize and thus be less likely to fire action potentials and contract (**Figure 48.8**). In contrast, norepinephrine acting through G protein-coupled receptors causes the smooth muscle in arteries serving the gut to contract. Remember that the action of the neurotransmitters depends on the receptors in the target tissues. Sympathetic activity is high in a fight-or-flight situation; in an emergency you don’t need to digest your lunch, but you do need to send blood to the tissues critical for survival.

Although smooth muscle cell contraction is not controlled by the troponin–tropomyosin mechanism, calcium still plays a critical role. A Ca^{2+} influx into the sarcoplasm of a smooth muscle cell can be stimulated by action potentials, hormones, or stretching. The Ca^{2+} that enters the sarcoplasm combines with a protein called calmodulin. The calmodulin– Ca^{2+} complex activates an enzyme called myosin kinase that phosphorylates myosin heads. When the myosin heads in smooth muscle are phosphorylated, they undergo cycles of binding and releasing actin, causing muscle contraction. As Ca^{2+} is removed from the sarcoplasm, it dissociates from calmodulin, and the activity of myosin kinase falls. An additional enzyme, myosin phosphatase, dephosphorylates the myosin to help reduce actin–myosin interactions (**Figure 48.9**).

Smooth Muscle Action
Life10e.com/at48.2

48.9 The Role of Ca^{2+} in Smooth Muscle Contraction When a smooth muscle cell is stimulated by neurotransmitter, Ca^{2+} enters the sarcoplasm and binds to calmodulin, which in turn activates an enzyme that phosphorylates the myosin heads, causing them to bind to actin. As long as the myosin remains phosphorylated, actin and myosin go through cycles of binding and release. Thus in smooth muscle the Ca^{2+} -mediated change is on myosin, whereas in skeletal and cardiac muscle it is on the actin–tropomyosin filament.

RECAP 48.1

The contractile ability of muscle derives from interactions between actin and myosin filaments. The three types of muscle are skeletal, cardiac, and smooth. Contraction in all three depends on control by Ca^{2+} in the sarcoplasm. Tropomyosin and troponin are controlling elements in skeletal and cardiac muscle. Calmodulin is the controlling element in smooth muscle.

- Explain how the cellular and subcellular structures of skeletal muscle relate to the sliding filament theory of muscle contraction. **See pp. 987–989 and Figures 48.1, 48.2, and 48.3**
- What is the role of Ca^{2+} in the contractile mechanism of skeletal, cardiac, and smooth muscle? **See pp. 989–990 and Figures 48.5 and 48.6**
- What roles does ATP play in the actin and myosin interactions that produce contraction? **See Figure 48.6**

Now that we understand how muscles generate force, we can look at what determines the characteristics of a muscle, its performance, and how individual muscles can change their characteristics with regular use and conditioning.

48.2 What Determines Skeletal Muscle Performance?

The functions that different muscles perform place different demands on them. Some muscles, such as postural muscles, must sustain a load continuously over long periods of time. Muscles used in locomotion and heavy work must be able to vary their strength of contraction over a wide range. Other muscles, such as those that control your fingers, generally do not have to sustain long, strong contractions, but they must be able to contract quickly. And what is “quick” for humans doesn’t begin to compare with insect flight muscles that can contract as fast as 1,000 times per second. How are muscles adapted to specific functions and demands?

The strength of a muscle contraction depends on how many fibers are contracting and at what rate

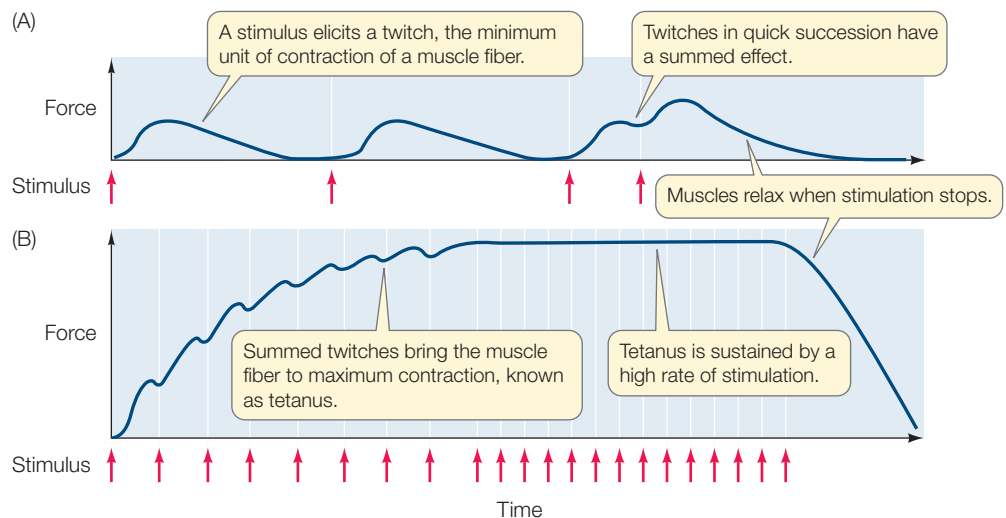

In skeletal muscle, the arrival of an action potential at a neuromuscular junction causes an action potential in a muscle fiber. The spread of that action potential through the muscle fiber’s T tubule system causes a minimum unit of contraction, called a **twitch**. A twitch can be measured in terms of the tension, or force, it generates (**Figure 48.10A**). A single action potential stimulates a single twitch, but the ultimate force generated by an action potential varies enormously depending on how many muscle fibers it reaches. The level of tension an entire muscle generates depends on two factors: the number of motor units activated, and the frequency at which the motor units fire.

In muscles responsible for fine movements, such as those of the fingers, a motor neuron may innervate only one or a few muscle fibers, but in a muscle that produces large forces, such as the biceps, a motor neuron innervates a large number of muscle fibers.

At the level of a muscle fiber, a single action potential stimulates a single twitch. If action potentials reaching the muscle fiber are adequately separated in time, each twitch is a discrete, all-or-none phenomenon. If action potentials are fired more rapidly, however, new twitches are triggered before the myofibrils have a chance to return to their resting condition. As a result, the twitches sum, and the tension generated by the fiber increases and becomes more sustained. Thus an individual muscle fiber can show a graded response to increased levels of stimulation by its motor neuron.

Twitches sum at high levels of stimulation because the calcium pumps in the sarcoplasmic reticulum (see Figure 48.5) are not able to clear the Ca^{2+} ions from the sarcoplasm between action potentials. Eventually a stimulation frequency can be reached that results in the continuous presence of Ca^{2+} in the sarcoplasm at high enough levels to cause continuous activation of the contractile machinery—a condition known as **tetanus** (**Figure 48.10B**). (Do not confuse this condition with the disease tetanus, which is caused by a bacterial toxin and is characterized by spastic contractions of skeletal muscles.)

48.10 Twitches and Tetanus (A) Action potentials from a motor neuron cause a muscle fiber to twitch. Twitches in quick succession can be summed. (B) Summation of many twitches can bring the muscle fiber to the maximum level of contraction, known as tetanus.

How long a muscle fiber can maintain a tetanic contraction depends on its supply of ATP. Eventually the fiber will become fatigued and be unable to sustain the contraction. It may seem paradoxical that the *lack* of ATP causes fatigue, since the action of ATP is to break actin–myosin bonds. But remember that the energy released from the hydrolysis of ATP “re-cocks” the myosin heads, allowing them to cycle through another power stroke. When a muscle is contracting against a load, the cycle of making and breaking actin–myosin bonds must continue in order to prevent the load from stretching the muscle. The situation is like rowing a boat upstream. You cannot maintain your position relative to the stream bank by just holding the oars out against the current; you have to keep rowing. Likewise, actin–myosin bonds have to keep cycling to maintain tension in the muscle.

Many muscles of the body maintain a low level of tension even when the body is at rest. For example, the muscles of the neck, trunk, and limbs that maintain our posture against the pull of gravity are always working, even when we are standing or sitting still. Muscle tone comes from the activity of a small but changing number of motor units in a muscle; at any one time, some of the muscle’s fibers are contracting and others are relaxed. The nervous system is constantly readjusting muscle tone.

Muscle fiber types determine endurance and strength

Not all skeletal muscle fibers are alike, and a single muscle often contains more than one type of fiber. The two major types of skeletal muscle fibers express different genes for their myosin molecules, and these myosin variants have different rates of ATPase activity. Those with high ATPase activity can recycle their actin–myosin cross-bridges rapidly and are therefore called fast-twitch fibers. Slow-twitch fibers have lower ATPase activity; they develop tension more slowly but can maintain it longer.

Slow-twitch fibers are also called oxidative or red muscle because they contain **myoglobin** (an oxygen-binding protein similar to the hemoglobin in red blood cells), have many mitochondria, and are well supplied with blood vessels. These characteristics both increase the fibers’ capacity for oxidative metabolism and result in their red appearance. The maximum tension a slow-twitch fiber produces is low and develops slowly but is highly resistant to fatigue. Slow-twitch fibers have substantial reserves of fuel (glycogen and fat), so they can maintain steady, prolonged production of ATP as long as oxygen is available. Muscles with high proportions of slow-twitch fibers are good for long-term aerobic work (that is, work that requires oxygen). Long-distance runners, swimmers, cyclists, and other athletes whose activities require endurance have leg and arm muscles consisting mostly of slow-twitch fibers (**Figure 48.11**).

Some **fast-twitch fibers** are also called glycolytic or white muscle because, compared with slow-twitch fibers, they have few mitochondria, little or no myoglobin, and fewer blood vessels; thus they look pale. Fast-twitch glycolytic fibers can develop maximum tension more rapidly than slow-twitch fibers can, and that maximum tension is greater. However, fast-twitch fibers fatigue rapidly. The myosin of these fibers puts the energy

(A) Cross sections of leg muscles

(B)

48.11 Slow- and Fast-Twitch Muscle Fibers (A) The skeletal muscles in the micrographs were stained with a reagent that shows slow-twitch fibers as dark and fast-twitch muscle as light. (B) Athletes in different sports have different distributions of muscle fiber types.

of ATP to work very rapidly, but the fibers cannot replenish ATP quickly enough to sustain contraction for a long time. Fast-twitch fibers are especially good for short-term work that requires maximum strength. Weight lifters and sprinters have leg and arm muscles with high proportions of fast-twitch fibers.

The types of fibers that make up a muscle influence the performance properties of that muscle, and different muscles have different fiber compositions depending on their function. Postural muscles that maintain continuous contractions are mostly composed of slow-twitch fibers. An example is the soleus muscle that runs up the back of the leg from the heel. Its contraction extends the foot and is therefore used in walking, but its continuous contraction is required for standing. If the soleus muscle fatigued, we would fall forward. A person can walk or stand for a long period of time because the soleus muscle is resistant to fatigue. In contrast, a muscle that is used mostly for short-term work, such as the biceps, has a higher percentage of fast-twitch fibers than does the soleus. We can use our biceps to pick up a heavy weight, but we cannot hold that weight in a given position for a long period of time.

Can you change the fiber composition of your muscles to optimize your performance in a particular activity? To a limited extent, you can alter the properties of your muscle fibers through training. There are fast-twitch fibers that are somewhat oxidative and therefore intermediate in their properties between slow-twitch and fast glycolytic fibers. These intermediate fibers can become more oxidative with endurance training and more glycolytic with strength training. However, the most important determinant of your muscle fiber types is your genetic heritage. There is some truth to the statement that champions are born, not made. A person born with a high proportion of fast-twitch fibers in her legs is unlikely to become a champion marathon runner, and a person born with a high proportion of slow-twitch fibers in her legs is unlikely to become a champion sprinter.

A muscle has an optimal length for generating maximum tension

If you have ever done a pull-up, you know that two parts of this exercise are especially difficult. When you are hanging from the bar with your arms fully extended, it is hard to get the pull-up started; and when your chin has just about reached the bar, pulling yourself up the last small distance is difficult. Why is this? Part of the explanation comes from the lever properties of the muscle–joint interaction that we will discuss in Section 48.3, and part comes from the structure of the sarcomere.

You can see the relationship between the length of a muscle fiber and its ability to develop tension in **Figure 48.12**. When a muscle is stretched and the sarcomeres are lengthened, there is less overlap between the actin and myosin filaments; therefore fewer cross-bridges can form, and less force can be produced. In fact, if the sarcomeres are stretched too much, actin and myosin do not overlap and no force can be produced. How would a muscle recover from such a difficult situation? Like a bungee cord, titin molecules create enough elastic recoil to pull the actin and myosin fibrils back into an overlapping arrangement.

When the muscle is fully contracted, the actin and myosin filaments overlap so much that the myosin bundles are pressed up against the Z lines. Because they have no place to go, additional shortening is difficult.

Exercise increases muscle strength and endurance

Different types of exercise produce different physical conditioning responses. In general, anaerobic activities, such as weight lifting, increase strength, and aerobic activities, such as jogging, increase endurance. Strength is the maximum force a muscle can exert, and endurance is work capacity or how long a given workload can be sustained. What are the physiological bases for these differences?

Strength is a function of the cross-sectional area of muscles: the more actin and myosin filaments in a muscle fiber, and the more muscle fibers in a muscle, the more tension it can

48.12 Force and Length The amount of force a sarcomere can generate depends on its resting length. When a muscle is stretched, the sarcomeres lengthen, there is less overlap between the actin and myosin filaments, and less force is produced. Overstretched sarcomeres produce no force because there is no overlap between the actin and myosin.

produce. When athletes undertake strength training, they use weights or exercises such as pull-ups to repeatedly contract specific muscles under heavy loads. Repetitions are usually done until the muscle is completely fatigued. Such stress on a muscle does minor tissue damage—hence the soreness the day after a hard workout—but it also induces the formation of new actin and myosin filaments in existing muscle fibers. The muscle fibers, and hence the muscles, get bigger and stronger. In extreme cases, and after serious muscle damage, new muscle fibers can also be produced from stem cells called satellite cells in the muscle. In general, however, the major effect of strength training is to produce bigger, rather than more, muscle fibers.

Aerobic exercise has a completely different effect on muscles: it enhances their oxidative capacity. This effect comes from increases in the number of mitochondria, in enzymes involved in energy use, and in the density of capillaries that deliver oxygen to the muscle. Myoglobin also increases in

skeletal muscle cells. Although it is similar to hemoglobin, myoglobin has a higher affinity for oxygen. Therefore myoglobin accepts oxygen from the blood, facilitates the diffusion of oxygen throughout the muscle, and provides a store of oxygen for use when oxygen delivery by the blood is insufficient. By increasing the capacity of muscle to use oxygen to produce ATP, aerobic training increases the length of time that a given workload can be sustained.

Muscle ATP supply limits performance

Muscles have three systems for supplying the ATP they need for contraction:

1. The *immediate system* uses preformed ATP and creatine phosphate.
2. The *glycolytic system* metabolizes carbohydrates to lactate and pyruvate.
3. The *oxidative system* metabolizes carbohydrates or fats all the way to H_2O and CO_2 .

The capacity of these three systems and the rates at which they can produce ATP determine both work capacity and endurance (Figure 48.13).

ATP is present in muscles in very small amounts. However, muscle fibers also contain a storage compound called creatine phosphate (CP). This molecule stores energy in a phosphate bond, which it can transfer to ADP. The total energy available in all the muscles of your body in the form of ATP and CP—the immediate energy system—is only about 10 kilocalories. When at rest, you metabolize a kilocalorie of energy in less than a minute. Even though the energy available from ATP and CP is limited, it is available immediately, and it enables fast-twitch fibers to generate a lot of force quickly. During burst activity, the immediate system is exhausted in seconds.

The glycolytic system activates within a few seconds to replace the ATP depleted at the onset of muscle activity. The glycolytic enzymes are located in the cytoplasm of the muscle fiber, and therefore the ATP they generate is rapidly available to the myosin filaments. However, as noted in Chapter 9, glycolysis alone is an inefficient way to produce ATP, and it leads to the accumulation of lactic acid, which slows the process. Thus the glycolytic system and the immediate system together can provide most of the energy for active muscles for less than a minute (see Figure 48.13).

Oxidative metabolism becomes fully active in about a minute, producing relatively huge amounts of ATP because it can completely metabolize carbohydrates and fats. However, it requires many reactions (see Section 9.3), and it takes place in the mitochondria, so O_2 and substrate must diffuse into the mitochondria, and the formed ATP must diffuse from the mitochondria to the myosin filaments in the muscle. These processes are not instantaneous, so the rate at which oxidative metabolism can make ATP available to do work is slower than the rate at which the other two systems can supply ATP.

The fuel supply available to the muscles influences how long someone can sustain a high level of aerobic exercise.

48.13 Supplying Fuel for High Performance (A) Muscles have three systems for obtaining the ATP they need for contraction during exertion such as running. (B) Looking at a plot of world-record times for running events of different durations, you can see that the performance of the athletes corresponds to the time courses of the three energy systems.

From the circulating blood, muscle receives glucose and free fatty acids, which it can metabolize to generate ATP. At high levels of aerobic exercise, however, most of the fuel used by muscles to produce ATP comes from the reserve of glycogen stored in the muscle itself. Depletion of muscle glycogen results in fatigue.

The rate at which muscle glycogen is replenished depends on diet: it is high with a high-carbohydrate diet, low with a high-fat diet, and intermediate with a mixed diet. This fact is the basis for a practice called “carbo-loading.” For 3 to 5 days, athletes exercise at a level that depletes muscle glycogen. Then, 2 or 3 days before the event, they taper down their level of training and eat a diet rich in complex carbohydrates. The result can be glycogen supercompensation, in which the restoration of muscle glycogen stores “overshoots” and reaches above-normal levels.

Insect muscle has the greatest rate of cycling

Insect flight muscle can produce a wingbeat frequency of up to 1,000 cycles per second. Since neural action potentials last 1 to 3

WORKING WITH DATA:

Does Heat Cause Muscle Fatigue?

Original Paper

Grahn, D. A., V. H. Cao, C. M. Nguyen, M. T. Lieu, and H. C. Heller. 2012. Work volume and strength training responses to resistive exercise improve with periodic heat extraction from the palm. *Journal of Strength and Conditioning Research*. Epub ahead of print. doi: 10.1519/JSC.0b013e31823f8c1a

Analyze the Data

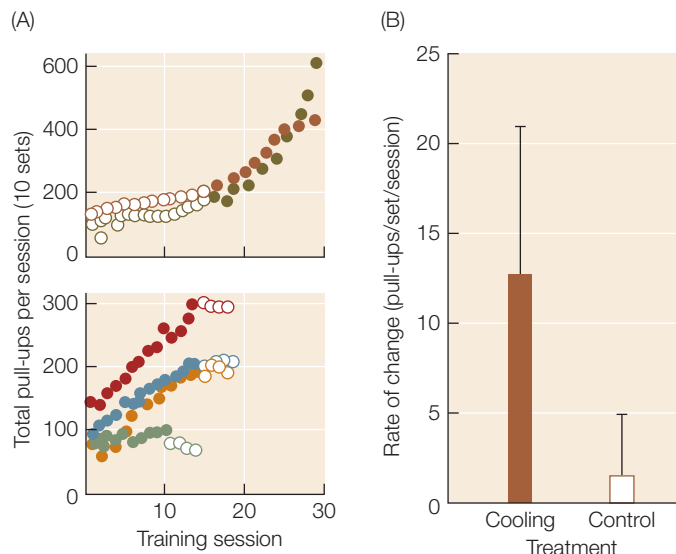

Physical conditioning requires repeated intense physical activity, and the capacity of such workouts is limited by muscle fatigue. Because metabolic heat production raises the temperature of muscles during workouts, it is possible that the rise in temperature contributes to muscle fatigue and limits the capacity of workouts. To test this idea, investigators used the rapid-cooling technology described in the opening of Chapter 40 to extract heat from subjects during 3-minute rests between ten sets of pull-ups twice a week. Each of the ten sets of pull-ups was to muscle failure—the inability to complete an additional pull-up. The control condition was 3-minute rests without cooling. Each subject was his own control; the subjects were randomly assigned to begin with 6 weeks of training with cooling or 6 weeks of training without cooling, followed by a reversal of the treatments. The results are shown in the figure.

QUESTION 1

What do these data indicate about the possible role of muscle temperature in muscle fatigue?

QUESTION 2

What do these data indicate about the relationship between workout capacity and physical conditioning effects?

THE EFFECT OF COOLING ON WORKOUT CAPACITY (A) The results for individual subjects. Open symbols indicate control treatment, closed symbols indicate cooling treatment; different colors indicate different subjects. (B) Regression analysis of the pull-up data, which shows the rate of increase in workout capacity over the course of the experiment. milliseconds, that number of cycles per second would push the capacity of motor neurons, let alone the mechanism of cycling of striated muscle contraction/relaxation. The extremely fast wingbeat of a hummingbird may only be about 50 cycles per second. How do insects do it?

The mechanism of excitation/contraction coupling is different in insect flight muscle. Vertebrate striated muscle and much of invertebrate striated muscle is called “synchronous” because the cycling of the contractile mechanism is linked to the firing of the motor neurons. This is not true of insect flight muscle, which is therefore called “asynchronous” muscle. The firing of action potentials in the insect flight motor neurons is not particularly fast, but it does cause depolarization of the muscle cell membrane, the spreading of an action potential throughout the membrane, and the release of Ca^{2+} from the sarcoplasmic reticulum. However, once the asynchronous muscle fiber is stimulated, its cycle of contraction/relaxation proceeds at its own characteristic frequency as long as the Ca^{2+} is available to bind to the troponin. The contraction of the muscle fiber deactivates the actin–myosin binding, which in turn permits a stretching of the muscle, which in turn activates the actin–myosin binding. Thus contractile cycling and the resulting wingbeat frequency are not tied to the firing rate of the flight motor neurons.

RECAP 48.2

Depending on the function a muscle serves, it may need to generate maximum force rapidly, sustain activity for a long period, or contract and relax at a very rapid rate. Properties of muscles can facilitate these types of activities.

- How can a single motor unit exert varying levels of force? **See p. 994 and Figure 48.10**
- Describe the differences between slow-twitch and fast-twitch fibers. **See p. 995 and Figure 48.11**
- How does exercise influence muscle strength and endurance? **See p. 996**
- How do the different sources of ATP influence performance in different types of exercise? **See p. 997 and Figure 48.13**
- Explain how insects can beat their wings ten or more times faster than hummingbirds can. **See p. 998**

Regardless of how much force a muscle can generate, how long it can sustain a workload, or how fast it can contract and relax, a muscle needs something to pull on; otherwise it would just be a lump of pulsating, quivering tissue. Let’s look now at how muscle and skeletal elements work together to produce movement.

48.3

How Do Skeletal Systems and Muscles Work Together?

Muscles can contract and exert force, or they can relax. To create significant movement, they must have something to pull on and something that stretches the muscle back to a longer position. In some cases muscles pull on each other, as in the trunk of an elephant or the arms of an octopus. In most cases, however, **skeletal systems** are the rigid supports against which muscles pull to create directed movement. In this section we will examine the three types of skeletal systems: hydrostatic skeletons, exoskeletons, and endoskeletons.

A hydrostatic skeleton consists of fluid in a muscular cavity

Cnidarians, annelids, and other soft-bodied invertebrates have **hydrostatic skeletons** consisting of a volume of fluid enclosed in a body cavity surrounded by muscle (see Section 31.2). When muscles oriented in one direction contract, the fluid-filled body cavity bulges out in a perpendicular direction.

An earthworm uses its hydrostatic skeleton to crawl (**Figure 48.14**). The earthworm's body cavity is divided into many separate segments filled with extracellular fluid. The body wall surrounding each segment has two muscle layers: a circular layer and a longitudinal layer. If the circular muscles in a segment contract, the compartment in that segment narrows and elongates. If the longitudinal muscles in a segment contract, the compartment shortens and bulges outward. Alternating contractions of the earthworm's circular and longitudinal muscles create waves of narrowing and widening, lengthening

48.14 A Hydrostatic Skeleton Alternating waves of muscle contraction move the earthworm through the soil. The red dot enables you to follow the changes in one segment as the worm moves forward.

and shortening, that travel down the body. Bulging, shortened segments serve as anchors as long, narrow segments project forward and longitudinal contractions pull other segments forward. Bristles help the widest parts of the body to hold firm against the substrate, so the body moves forward.

Exoskeletons are rigid outer structures

An **exoskeleton** is a hardened, rigid outer surface to which muscles can be attached. Contractions of the muscles cause jointed segments of the exoskeleton to move relative to each other. The simplest example of an exoskeleton is the shell of a mollusk. Some marine mollusks, such as clams, have shells composed of protein strengthened by crystals of calcium carbonate (a rock-hard material). These shells can be massive, affording significant protection against predators. The shells of land mollusks (snails) generally lack the hard mineral component and are much lighter.

The most complex exoskeletons are found among the arthropods. A type of exoskeleton called a **cuticle** covers the outer surfaces of the arthropod body and all its appendages. It is made up of **chitin** secreted by a layer of cells just below the exoskeleton. Chitin stiffens and hardens the cuticle everywhere except at the joints, where flexibility must be retained. Muscles attached to the inner surfaces of the arthropod cuticle move its parts around the joints (see Figure 32.4).

A drawback of the rigid arthropod exoskeleton is that it cannot expand. Therefore, if the animal is to become larger, it must **molt**, shedding its exoskeleton and forming a new, larger one. A molting animal is vulnerable because the new exoskeleton takes time to harden. The animal's body is temporarily unprotected, and without a firm exoskeleton against which its muscles can exert maximum tension, it is unable to move rapidly. Soft-shelled crabs, a gourmet delicacy, are crabs caught while they are molting.

Vertebrate endoskeletons consist of cartilage and bone

The **endoskeleton** of vertebrates is an internal scaffolding. Muscles are attached to it and pull against it. Endoskeletons are composed of rodlike, platelike, and tubelike bones connected to one another at a variety of joints that allow a wide range of movements. An advantage of endoskeletons over the exoskeletons of arthropods is that bones in the body can grow without the animal shedding its skeleton.

The human skeleton consists of 206 bones, some of which are shown in **Figure 48.15**. It can be divided into an axial skeleton, which includes the skull, vertebral column, sternum, and ribs; and an appendicular skeleton, which includes the pectoral girdle, pelvic girdle, and bones of the arms, legs, hands, and feet.

The vertebrate endoskeleton consists of two kinds of connective tissue, cartilage and bone, which are produced by two kinds of connective tissue cells. Cartilage cells produce an extracellular matrix that is a tough, rubbery mixture of polysaccharides and proteins—mainly fibrous collagen. Collagen fibers run in all directions like reinforcing cords through the gel-like matrix and give it the well-known strength and resiliency of

48.15 The Human Endoskeleton Cartilage and bone make up the internal skeleton of a human being.

“gristle.” This matrix, called **cartilage**, is found in parts of the endoskeleton where both stiffness and resiliency are required, such as on the surfaces of joints where bones move against one another. Cartilage is also the supportive tissue in stiff but flexible structures such as the larynx (voice box), nose, and ear pinnae. Sharks and rays are called cartilaginous fishes because their skeletons are composed entirely of cartilage. In most other vertebrates, cartilage is the principal component of the embryonic skeleton, but during development most of it is gradually replaced by bone.

Bone also contains collagen fibers, but it gets its rigidity and hardness from an extracellular matrix of insoluble calcium phosphate crystals. Bone serves as a reservoir of calcium for the rest of the body and is in dynamic equilibrium with soluble calcium in the extracellular fluids of the body. This equilibrium is under the control of calcitonin and parathyroid hormone (see Figure 41.14). If too much calcium is taken from the skeleton, the bones are seriously weakened.

The living cells of bone—osteoblasts, osteocytes, and osteoclasts—are responsible for the constant dynamic remodeling of

48.16 Bone Is Living Tissue Bones are constantly being remodeled by osteoblasts, which lay down bone, and osteoclasts, which resorb bone.

bone (**Figure 48.16**). **Osteoblasts** lay down new matrix material on bone surfaces. These cells gradually become surrounded by matrix and eventually become enclosed within the bone, at which point they cease laying down matrix but continue to exist within small lacunae (cavities) in the bone. In this state they are called **osteocytes**. Despite the vast amounts of matrix between them, osteocytes remain in contact with one another through long cellular extensions that run through tiny channels in the bone. Communication between osteocytes is important in controlling the activities of the cells that are laying down or removing bone.

The cells that resorb bone are the **osteoclasts**. They are derived from the same cell lineage that produces white blood cells. Osteoclasts erode bone, forming cavities and tunnels. Osteoblasts follow osteoclasts, depositing new bone. Thus the interplay of osteoblasts and osteoclasts constantly replaces and remodels the bones, allowing a bone to recover from damage and adjust to the forces placed on it.

How the activities of the bone cells are coordinated is not understood, but stress placed on bones somehow provides them with information. A remarkable finding in studies of astronauts who spent long periods in zero gravity was that their bones decalcified. Conversely, in athletes, certain bones thicken during training. Both thickening and thinning of bones are experienced by anyone who has had a leg in a cast for a long time: the bones of the uninjured leg carry the person’s weight and thicken while the bones of the inactive leg in the cast thin.

Because of the positive effects of physical stress on bone deposition, weight-bearing exercise is effective in preventing and treating osteoporosis, which is the loss of bone density (and hence strength). More than 25 million people in the United States suffer from this debilitating condition. Although osteoporosis is most commonly a problem for postmenopausal women, it can occur in younger people as a result of malnutrition. For example, the condition known as female athlete triad includes

eating disorders, cessation of menstrual cycling, and osteoporosis. These are interactive conditions in which the eating disorder and excessive training lead to malnutrition that can result in endocrine disruption and osteoporosis. Excessive training and malnutrition can lead to bone loss in males as well.

Bones develop from connective tissues

Bones are divided into two types on the basis of how they develop. **Membranous bone** forms on a scaffold of connective tissue membrane. **Cartilage bone** forms first as a cartilaginous structure resembling the future mature bone, then gradually hardens, or ossifies, to become bone. The outer bones of the skull are membranous bones; the bones of the limbs are cartilage bones.

Cartilage bones can grow throughout the ossification process. The long bones of the legs and arms, for example, ossify first at the centers and later at each end (Figure 48.17). Growth can continue until these areas of ossification join. The membranous bones forming the skull cap grow until their edges meet.

48.17 The Growth of Long Bones In the long bones of human limbs, ossification occurs first at the centers and later at each end.

48.18 Most Compact Bone Is Composed of Haversian Systems

A micrograph of a section of a long bone shows Haversian systems with their central canals. Glue lines separate Haversian systems.

The soft spot on the top of a baby's head (the fontanelle) is the point at which the skull bones have not yet joined.

The structure of bone may be **compact** (solid and hard) or **cancellous** (having numerous internal cavities that make it appear spongy, although it is rigid). The architecture of a specific bone depends on its position and function, but most bones have both compact and cancellous regions. The shafts of the long bones of the limbs, for example, are cylinders of compact bone surrounding central cavities that contain the bone marrow, where the cellular elements of the blood are made. The ends of the long bones are cancellous (see Figure 48.17). Cancellous bone is lightweight because of its numerous cavities, but it is also strong because its internal meshwork constitutes a support system. It can withstand considerable forces of compression. The rigid, tubelike shaft of compact bone can withstand compression and bending forces. Architects and nature alike use hollow tubes as lightweight structural elements.

Most of the compact bone in mammals is called Haversian bone because it is composed of structural units called **Haversian systems** (Figure 48.18). Each Haversian system is a set of thin, concentric bony cylinders, between which are the osteocytes in their lacunae. Through the center of each Haversian system runs a narrow canal containing blood vessels and nerves. Adjacent Haversian systems are separated by boundaries called glue lines. Haversian bone is resistant to fracturing because cracks tend to stop at glue lines.

Bones that have a common joint can work as a lever

Muscles and bones work together around **joints**, where two or more bones come together. Different kinds of joints allow motion in different directions (Figure 48.19), but muscles can exert force in only one direction. Therefore muscles create

48.19 Types of Joints The designs of joints are similar to mechanical counterparts and enable a variety of movements.

Go to Activity 48.3 Joints

Life10e.com/ac48.3

movement around joints by working in antagonistic pairs: when one muscle contracts, the other relaxes. When both contract, the joint becomes rigid (which is important for maintaining posture, for example).

With respect to a particular joint, such as the knee, we refer to the muscle that bends, or flexes, the joint as the **flexor**, and the muscle that straightens, or extends, the joint as the **extensor**. The bones that meet at the joint are held together by **ligaments**, which are flexible bands of connective tissue. Other straps of connective tissue, called **tendons**, attach the muscles to the bones (Figure 48.20). In many kinds of joints, only the tendon spans the joint, sometimes moving over the surfaces of the bones like a rope over a pulley. The tendon of the quadriceps muscle traveling over the knee joint is what is tapped to elicit the knee-jerk reflex (see Figure 45.18).

Bones constitute a system of levers that are moved around joints by the muscles. A

48.20 Joints, Ligaments, and Tendons A side view of the knee shows the interactions of muscle, bone, cartilage, ligaments, and tendons at this crucial and vulnerable human joint.

lever has an effort arm and a load arm that work around a fulcrum (pivot). The length ratio of the two arms determines whether a particular lever can exert a lot of force over a short distance or is better at translating force into large or fast movements. Compare the jaw and knee joints, for example (Figure 48.21). The effort arm of the jaw is long relative to the load arm, allowing the jaw to apply great force over a small distance. Think of the powerful jaws of carnivores that can easily crack bones. The effort arm of the lower leg, by contrast, is short relative to the load arm, so you can run fast, jump high, and deliver swift kicks.

48.21 Bones and Joints Work Like Systems of Levers A lever system can be designed for maximizing either force or speed.

RECAP 48.3

Muscles can only contract and relax; to achieve organized movement, they must pull against rigid structures—other muscles, hydrostatic skeletons, exoskeletons, or endoskeletons.

- How do the muscles and fluid-filled body cavity of an earthworm interact to enable the animal to move? **See p. 999 and Figure 48.14**
- In terms of levers, explain how specific joints can produce maximum force versus maximum speed. **See p. 1002 and Figure 48.21**

How can the kangaroo increase its speed fivefold without increasing its metabolic expenditure?

ANSWER

In kangaroos, as in other vertebrates, the muscles used to jump are attached to bones by tendons. Tendons are elastic. The kangaroo's tendons stretch when it lands, and their recoil helps power the next jump—similar to the action of a pogo stick. To move faster, the kangaroo simply increases the length of its stride, thereby increasing both the stretch on its tendons each time it lands and the magnitude of the recoil at the initiation of each jump.

CHAPTERSUMMARY 48

48.1 How Do Muscles Contract?

- **Skeletal muscle** consists of bundles of **muscle fibers**. Each skeletal muscle fiber is a large cell containing multiple nuclei.
- Skeletal muscles contain numerous **myofibrils**, which are bundles of **actin** and **myosin** filaments. The regular, overlapping arrangement of the actin and myosin filaments into **sarcomeres** gives skeletal muscle its striated appearance. **Review Figure 48.1, ACTIVITY 48.1**
- The changes in the banding patterns of sarcomeres led to the **sliding filament model** of muscle contraction. **Review Figure 48.2**
- The molecular mechanism of muscle contraction involves the binding of the globular heads of myosin molecules to actin. **Review Figures 48.3, 48.6, ANIMATED TUTORIAL 48.1**
- All the fibers activated by a single motor neuron constitute a **motor unit**. Each nerve ending of the motor neuron forms a synapse with the muscle cell membrane. Action potentials spread across the muscle cell membrane and through the **T tubules**, causing Ca^{2+} to be released from the **sarcoplasmic reticulum**. **Review Figure 48.5, ACTIVITY 48.2**
- Ca^{2+} binds to **troponin** and changes its conformation, pulling the **tropomyosin** strands away from the myosin-binding sites on the actin filament. The muscle fiber continues to contract until the Ca^{2+} is returned to the sarcoplasmic reticulum. **Review Figure 48.6**
- **Cardiac muscle** cells are striated, uninucleate, branching, and electrically connected by gap junctions, so that action potentials spread rapidly throughout sheets of cardiac muscle and cause coordinated contractions.
- **Smooth muscle** provides contractile force for internal organs. Smooth muscle cells respond to stretch and to neurotransmitters from the autonomic nervous system. **Review Figure 48.8, ANIMATED TUTORIAL 48.2**

48.2 What Determines Muscle Performance?

- In skeletal muscle, a single action potential causes a minimum unit of contraction called a **twitch**. Twitches occurring in rapid succession can be summed to achieve sustained tension, known as **tetanus**. **Review Figure 48.10**
- **Slow-twitch fibers** facilitate extended, aerobic work; **fast-twitch fibers** generate maximum forces for short periods of

time. The ratio of slow-twitch to fast-twitch fibers in the muscles of an individual is largely genetically determined. **Review Figure 48.11**

- The force that a muscle fiber can produce depends on its initial state of extension or contraction. **Review Figure 48.12**
- Anaerobic exercise stimulates the enlargement of muscle fibers through production of new microfilaments. Aerobic exercise stimulates greater oxidative capacity of muscle fibers.
- Muscle performance depends on a supply of ATP. **Review Figure 48.13**

48.3 How Do Skeletal Systems and Muscles Work Together?

- **Skeletal systems** provide supports against which muscles can pull.
- **Hydrostatic skeletons** are fluid-filled body cavities that can be squeezed by muscles. **Review Figure 48.14**
- **Exoskeletons** are hardened outer surfaces to which internal muscles are attached.
- **Endoskeletons** are internal systems of rigid rodlike, platelike, and tubelike supports, consisting of **bone** and **cartilage** to which muscles are attached. **Review Figure 48.15**
- Bone is continually remodeled by **osteoblasts**, which lay down new bone, and **osteoclasts**, which erode bone. **Review Figure 48.16**
- Bones develop from connective tissue membranes (**membranous bone**) or from cartilage (**cartilage bone**) through ossification. **Review Figure 48.17**
- Bone can be **compact** (solid and hard) or **cancellous** (containing numerous internal spaces). Most of the compact bone of mammals is composed of **Haversian systems**. **Review Figure 48.18**
- **Joints** enable muscles to power movements in different directions. Muscles and bones work together around joints as systems of levers. **Review Figures 48.19, 48.21, ACTIVITY 48.3**
- **Tendons** connect muscles to bones; **ligaments** connect bones to one another. **Review Figure 48.20**

CHAPTER REVIEW

REMEMBERING

- The role of Ca^{2+} in the control of muscle contraction is to
 - cause depolarization of the T tubule system.
 - change the conformation of troponin, thus exposing myosin-binding sites.
 - change the conformation of myosin heads, thus causing microfilaments to slide past each other.
 - bind to tropomyosin and break actin–myosin cross-bridges.
 - block the ATP-binding site on myosin heads, enabling muscles to relax.
- Fifteen minutes into a 10-kilometer run, what is the major energy source of the leg muscles?
 - Preformed ATP
 - Glycolysis
 - Oxidative metabolism
 - Pyruvate and lactate
 - High-protein drink consumed right before the race
- Which statement about skeletal muscle contraction is *not* true?
 - A single action potential at the neuromuscular junction is sufficient to cause a muscle to twitch.
 - Once maximum muscle tension is achieved, no ATP is required to maintain that level of tension.
 - An action potential in the muscle cell activates contraction by releasing Ca^{2+} into the sarcoplasm.
 - Summation of twitches leads to a graded increase in the tension that can be generated by a single muscle fiber.
 - The tension generated by a muscle can be varied by controlling how many of its motor units are active.
- Which statement about the structure of skeletal muscle is true?
 - The light bands of the sarcomere are the regions where actin and myosin filaments overlap.
 - When a muscle contracts, the A bands of the sarcomere lengthen.
 - The myosin filaments are anchored in the Z lines.
 - When a muscle contracts, the H zone of the sarcomere shortens.
 - The sarcoplasm of the muscle cell is contained within the sarcoplasmic reticulum.
- Insects can beat their wings at exceptionally high frequencies because
 - their wing muscles have mostly fast-twitch fibers.
 - their motor neurons can fire action potentials at a very high frequency.
 - their wings have exoskeletal supports.
 - their wing muscles have extensive sarcoplasmic reticulum that cycles Ca^{2+} very fast.
 - their wing muscles can generate a rapid oscillation of contraction that is asynchronous with motor neuron firing.

UNDERSTANDING & APPLYING

- Sarcomeres can shorten only by less than 50 percent of their resting length. Yet muscles cause movements of a wide range of magnitudes—compare the range of movement of a toe and a leg. What are two design features of muscles and skeletons that can maximize a muscle's ability to produce a wide range of movements of an appendage?
- If an adolescent breaks a leg bone close to the ankle joint, after the break heals, that leg may not grow as long as the other one. Why?
- Stand with your arms held out at right angles to your body for as long as you can. Which will fatigue first: your shoulders or your legs? Why? What does this tell you about the muscles of your shoulders and legs?

ANALYZING & EVALUATING

- A single action potential in a muscle cell lasts about 2 milliseconds, but the single muscle twitch it generates reaches its peak after about 30 msec, and does not return to resting level until about 150 msec after the action potential. Explain three factors that explain the time difference between the action potential and the twitch.
- Malignant hyperthermia is a rare but frequently lethal condition stimulated by certain anesthetics. Suddenly the individual's muscles become rigid, heart rate shoots up, and body temperature rises rapidly. Those at risk for malignant hyperthermia have a mutation in the gene that codes for the ryanodine receptor. The mutation results in excessive opening of the Ca^{2+} channels in the sarcoplasmic reticulum. Knowing this cause of the condition, how can you explain all of its manifestations—temperature, heart rate, and muscle tension?

Gas Exchange

CHAPTER OUTLINE

- 49.1** What Physical Factors Govern Respiratory Gas Exchange?
- 49.2** What Adaptations Maximize Respiratory Gas Exchange?
- 49.3** How Do Human Lungs Work?
- 49.4** How Does Blood Transport Respiratory Gases?
- 49.5** How is Breathing Regulated?

ELEPHANT TRUNKS HAVE MANY USES. They can pluck leaves, pull up plants, and pick up peanuts and tree trunks; they suck in water to squirt into the mouth for drinking or to spray over the body for cooling; they smell the air around them; they communicate by touch; and mothers can wallop their calves when they misbehave.

Of course, elephants also use their trunks to breathe, and it is a useful appendage indeed when they go into deep water—for example, to cross rivers. Whether the elephant swims or walks on the bottom, it uses its trunk as a snorkel. As long as the tip of the trunk is above water, the elephant can breathe.

You may be familiar with diving using a snorkel about a foot long. When you want to dive deeper, you hold your breath. Water is heavy, and as you swim deeper, water pressure increases and presses on your body. The air in your lungs is compressible, so as you swim deeper, the volume of your lungs decreases.

Think what would happen if you tried to suck air through a long snorkel in deep water. Because the snorkel would be open to the air above, the pressure in your lungs would be the same as at the water surface, but the surrounding water would be pressing on your body. To expand your lungs, you would have to exert enough force to push against the surrounding water. Not so easy! We solve this problem with scuba equipment: by breathing air from a pressurized tank with a regulator valve, we keep the air in our lungs at the same pressure as the surrounding water.

Proboscis as Snorkel Elephants can cross deep bodies of water either swimming or by walking on the bottom—whichever allows it to keep its trunk above water.

The chest of a snorkeling elephant can be 3 meters below the surface—and for every 3 meters, water pressure increases by 0.3 atmospheres (about 5 pounds per square inch, PSI). Even though the elephant's respiratory muscles are strong enough to work against this pressure, there is still a serious problem for the blood vessels lining the cavity in which the lungs are suspended. The pressure difference across the walls of those blood vessels is the difference between the pressure in the vessels (blood pressure plus the compressive water pressure) and the air pressure at the water surface (where the trunk opens to the air). This difference is at least 5 PSI—a pressure that in other mammals would burst small blood vessels and fill the chest cavity with blood.

How do elephants avoid damage to the blood vessels of their thoracic cavities when they snorkel?

See answer on p. 1022.

49.1 What Physical Factors Govern Respiratory Gas Exchange?

The **respiratory gases** that animals must exchange are oxygen (O_2) and carbon dioxide (CO_2). Cells need to obtain O_2 from the environment to produce an adequate supply of ATP by cellular respiration (see Chapter 9). CO_2 is an end product of cellular respiration, and it must be removed from the body to prevent toxic effects. Gas exchange systems of animals consist of (1) specialized body surface areas where these gases can move between the body and the environment, and (2) mechanisms that ventilate the environmental side of those surfaces with air or water and perfuse the internal side of those surfaces with extracellular fluids.

Diffusion is the only means by which respiratory gases are exchanged between an animal's internal body fluids and the outside medium (air or water). There are no active transport mechanisms to move respiratory gases across biological membranes. Because diffusion is a physical process, knowing what physical factors influence rates of diffusion helps us understand the diverse adaptations of gas exchange systems. (You may want to review the discussion about the physical nature of diffusion in Section 6.3.)

Diffusion of gases is driven by partial pressure differences

Diffusion results from the random motion of molecules, and the net movement of molecules within a medium such as air or water is down their concentration gradient. Concentrations in solutions are simply the amount of solute per volume of solution. Concentrations of gases, however, vary with pressure because gases are compressible. For example, there are twice as many gas molecules in a liter of gas at 2 atmospheres of pressure as there are in a liter of gas at 1 atmosphere of pressure.

Biologists express the concentrations of different gases in a mixture as the **partial pressures** of those gases. To calculate the partial pressure of a gas such as oxygen in a mixture of gases such as air, we have to know the total pressure. In most cases, for an air-breathing animal the total pressure is atmospheric pressure. At sea level, atmospheric pressure is about 760 millimeters of mercury (mm Hg), depending on the weather. Because dry air is 20.9 percent O_2 , the partial pressure of oxygen (P_{O_2}) at sea level is 20.9 percent of 760 mm Hg, or about 159 mm Hg. If two gas mixtures are separated by a membrane permeable to O_2 , O_2 will diffuse from the mixture where its partial pressure is higher to the mixture where its partial pressure is lower.

To calculate the concentration of a gas in a solution, we have to know the solubility of that gas in that particular solvent. The amount of a gas in a liquid depends both on its partial pressure in the gas phase in contact with the liquid *and* on its solubility in that liquid. The bottom line is that diffusion of a gas between the gas phase and the liquid phase is a function of its partial pressures in those two phases; the gas diffuses from the phase with the higher partial pressure to the phase with the lower partial pressure, and at equilibrium the partial pressures

in the two phases are equal. However, the *amount* of the gas that can be contained by the liquid depends on the solubility of that gas in that liquid. Furthermore, the solubility of a gas in a particular liquid can vary widely depending on conditions. What follows is a practical illustration of these facts.

Solubility of a gas in a liquid, such as oxygen in water, is a function of temperature—solubility is higher at low temperatures. So if we have similar containers of water in equilibrium with air, but at different temperatures, the concentrations of oxygen in these water containers will be different (less O_2 in the warmer ones), but the partial pressures of oxygen will be the same. Thus for water-breathing animals, the warmer the water is, the less O_2 there is per liter of water. The important point is that for a gas in solution, its concentration is not the same as its partial pressure, but partial pressures are what drive diffusion. Thus in our continuing discussions of respiratory gas exchange, we will always use partial pressure rather than concentration when referring to the amount of gas in solution.

Fick's law applies to all systems of gas exchange

Whether in air or water, the diffusion rates of respiratory gases depend on their partial pressure gradients and on other factors that can be described quantitatively with a simple equation called **Fick's law of diffusion**. All environmental variables that limit respiratory gas exchange and all adaptations that maximize respiratory gas exchange are reflected in one or more components of this equation. Fick's law is written as

$$Q = DA \frac{P_1 - P_2}{L}$$

where

- Q is the rate at which a gas such as O_2 diffuses between two locations
- D is the diffusion coefficient, which is a characteristic of the diffusing substance, the medium, and the temperature. For example, perfume has a higher D than motor oil vapor, and all substances diffuse faster at higher temperatures and faster in air than in water. Temperature is not expressed explicitly in Fick's law because the diffusion coefficient is usually determined at room temperature (about 20°C)
- A is the area across which the gas is diffusing
- P_1 and P_2 are the partial pressures of the gas at the two locations
- L is the path length, or distance, between the two locations
- $(P_1 - P_2)/L$ is a partial pressure gradient.

The strict dependence of animals on diffusion for gas exchange with their environments has selected for various adaptations that maximize Q , many of which we will describe in this chapter. Animals can maximize D for respiratory gases by using air rather than water as their gas exchange medium whenever possible. All other adaptations for maximizing respiratory gas exchange must influence the surface area (A) for gas exchange or the partial pressure gradient across that surface area.

Air is a better respiratory medium than water

The slow diffusion of O_2 molecules in water affects both air- and water-breathing animals. Eukaryotic cells carry out cellular respiration in their mitochondria, which are located in the cytoplasm—an aqueous medium. Cells are bathed in extracellular fluid—also an aqueous medium. In addition, all respiratory surfaces must be protected from drying out by a thin film of fluid through which O_2 must diffuse. Even in air-breathing animals, the slow rate of O_2 diffusion in water limits the efficiency of O_2 distribution from gas exchange surfaces to the sites of cellular respiration.

Diffusion of O_2 in water is so slow that even animal cells with low rates of metabolism cannot function more than a few millimeters away from a good source of environmental O_2 . Therefore there are severe size and shape limits on the many species of invertebrates that lack internal systems for distributing O_2 . Most of these species are very small, but some have grown larger by evolving a flat, thin body with a large external surface area (Figure 49.1A). Others have a very thin body built around a central cavity through which water can circulate (Figure 49.1B). A critical factor enabling larger, more complex animal bodies has been the evolution of specialized respiratory systems with large surface areas that are highly permeable to respiratory gases (Figure 49.1C).

O_2 can be obtained more easily from air than from water for several reasons:

- The O_2 content of air is much higher than the O_2 content of an equal volume of water. The maximum O_2 content of a bubbling stream in equilibrium with air is less than 10 milliliters of O_2 per liter of water. The O_2 content of the air over the stream is about 200 ml of O_2 per liter of air.
- O_2 diffuses about 8,000 times more rapidly in air than in water. That is why the O_2 content of a stagnant pond can be zero only a few millimeters below the surface.
- An animal has to work (expend energy) to ventilate its gas exchange surfaces with water or air. More energy is required to move water than air because water is 800 times denser than air and about 50 times more viscous.

You can appreciate how important these facts were for the evolutionary transition of life to the terrestrial environment, because they meant that there were fewer constraints on the evolution of higher metabolic rates.

High temperatures create respiratory problems for aquatic animals

Animals that use water for their respiratory exchange medium are in a double bind when environmental temperatures rise. Most water-breathing animals are ectotherms—their body temperatures are closely tied to the temperature of the water around them. As the water temperature rises, an ectotherm's body temperature and metabolic rate rise (see Figure 40.8). Thus water breathers need more O_2 as the water gets warmer

(A) *Pseudobiceros* sp.

Central cavity Channels

Gills

(C) *Ambystoma mexicanum*

49.1 Keeping in Touch with the Medium (A) No cell in the leaf-like body of this marine flatworm is more than a millimeter away from seawater. (B) Sponges have body walls perforated by many channels, which allow water to flow between the outside world and a central cavity. No cell in the sponge is more than a millimeter away from seawater. (C) A feathery fringe of gills on this aquatic salamander provides a large surface area for gas exchange. Blood circulating through the gills comes into close contact with the respiratory medium.

(Figure 49.2). But as mentioned above, warm water holds less dissolved gas than cold water does (think of the gases that escape when you open a warm bottle of soda). In addition, since a water-breathing animal performs work to move water across its gas exchange surfaces, it must expend more energy to breathe as water temperature rises. Therefore, as water temperature goes up, a water-breathing animal must extract more and more O_2 from an environment that is increasingly O_2 deficient, and a lower percentage of that O_2 is available to support activities other than breathing.

O_2 availability decreases with altitude

Just as a rise in water temperature reduces the supply of O_2 available to water-breathing animals, an increase in altitude reduces the O_2 supply for air breathers. At all altitudes, O_2 makes up 20.9 percent of the dry air; however, as you go up in altitude, the total amount of gas per unit of volume decreases, as reflected in the atmospheric pressure. For example, at 5,800 meters, atmospheric pressure is only half what it is at sea level,

49.2 The Double Bind of Water Breathers Fishes need more O_2 when the water is warmer, but warm water carries less O_2 than cold water.

so the P_{O_2} at that altitude is only about 80 mm Hg. At the summit of Mount Everest (8,850 m), P_{O_2} is only about 50 mm Hg—roughly one-third what it is at sea level.

Because the movement of O_2 across respiratory gas exchange surfaces and into the body depends on diffusion, its rate of movement depends on the P_{O_2} difference between the air and the body fluids. Therefore the drastically reduced P_{O_2} in the air at high altitudes constrains O_2 uptake. Because of this, mountain climbers attempting the highest peaks usually breathe O_2 from pressurized bottles.

CO_2 is lost by diffusion

Respiratory gas exchange is a two-way process: CO_2 diffuses out of the body as O_2 diffuses in. The direction and rate of diffusion of the respiratory gases across the exchange surfaces depend on the partial pressure gradients of the gases. The partial pressure gradients of O_2 and CO_2 across these exchange surfaces are quite different. The amount of CO_2 in the atmosphere is extremely low (0.03%), so for air-breathing animals there is always a large concentration gradient for diffusion of CO_2 from the body to the environment. Whereas the partial pressure gradient for O_2 decreases with increasing altitude, the gradient driving CO_2 out of the body hardly changes. The partial pressure of carbon dioxide (P_{CO_2}) in the atmosphere is close to zero both at sea level and atop Mount Everest.

In general, getting rid of CO_2 is not a problem for water-breathing animals because CO_2 is much more soluble in water than is O_2 . Even in stagnant water, where the P_{CO_2} is higher than in moving water, the lack of O_2 becomes a problem for an animal long before CO_2 exchange difficulties arise.

RECAP 49.1

Respiratory gases are exchanged only by diffusion. Air is a better respiratory medium than water because a given volume of air has more O_2 than the same volume of water. O_2 diffuses faster in air than in water, and less work is required to move air over respiratory exchange surfaces.

- Describe how the variables in Fick's law of diffusion relate to respiratory systems. **See p. 1006**
- Why does a rise in water temperature create a double-bind situation for water-breathing animals? **See p. 1007 and Figure 49.2**
- Explain the concept of partial pressures of gases and how it relates to diffusion rates of O_2 and CO_2 at different altitudes. **See pp. 1006 and 1007–1008**

Now that we have discussed the physical factors that influence diffusion rates of respiratory gases between animals and their environments, let's look at some of the adaptations that have evolved for maximizing respiratory gas exchange.

49.2 What Adaptations Maximize Respiratory Gas Exchange?

As you might expect from the components of Fick's law of diffusion, adaptations to maximize respiratory gas exchange can be categorized as those that:

- Increase the surface area for gas exchange (A)
- Maximize the partial pressure difference driving diffusion ($P_1 - P_2$)
- Minimize the diffusion path length (L)
- Minimize the diffusion that takes place in an aqueous medium (maximize D)

Respiratory organs have large surface areas

A variety of anatomical adaptations maximize the specialized body surface areas (A) for respiratory gas exchange. Water-breathing animals generally have gills, and air-breathing animals have tracheae or lungs. **External gills** are highly branched and folded extensions of the body surface that provide a large surface area for gas exchange (**Figure 49.3A**; see also **Figure 49.1C**). External gills are found in larval amphibians and in the larvae of many insects. Because they consist of thin, delicate tissues, external gills minimize the path length (L) traversed by diffusing molecules of O_2 and CO_2 . External gills are vulnerable to damage, however, and are tempting morsels for predators, so in many animals protective body cavities for gills have evolved. Such **internal gills** are found in most mollusks and arthropods and in all fishes (**Figure 49.3B**).

Lungs are internal cavities for respiratory gas exchange with air (**Figure 49.3C**). Their structure is quite different from that of gills. Lungs have a large surface area because they are highly divided; and because they are elastic, they can be inflated with air and deflated.

49.3 Gas Exchange Systems Large surface areas (blue in these diagrams) for the diffusion of respiratory gases are common features of animals. External (A) and internal (B) gills are adaptations for gas exchange with water. Lungs (C) and tracheae (D) are organs for gas exchange with air.

Insects have a respiratory gas exchange system consisting of a network of air-filled tubes called **tracheae** that branch through all tissues of the insect's body (**Figure 49.3D**). The terminal branches of these tubes are so numerous that they have an enormous surface area compared with the external surface area of the insect's body.

Ventilation and perfusion of gas exchange surfaces maximize partial pressure gradients

Partial pressure gradients $[(P_1 - P_2)/L]$ drive diffusion across gas exchange surfaces; the larger the gradient, the greater the rate of gas exchange. These gradients can be maximized in several ways:

- **Minimization of path length:** Very thin tissues in gills and lungs reduce the diffusion path length (L).

- **Ventilation:** Actively moving the external medium over the gas exchange surfaces (i.e., breathing) regularly exposes those surfaces to fresh respiratory medium containing maximum O_2 and minimum CO_2 concentrations. This maximizes the partial pressure gradients.
- **Perfusion:** Actively moving the internal medium (e.g., blood) over the internal side of the exchange surfaces transports CO_2 to those surfaces and O_2 away from them, thus maximizing the partial pressure gradients driving diffusion.

This chapter describes four gas exchange systems. First we will look at the unique gas exchange system of insects. Then we will describe two highly efficient gas exchange systems, fish gills and bird lungs. Lastly we will examine the structure and function of human lungs.

Insects have airways throughout their bodies

The tracheal system that enables insects to exchange respiratory gases extends to all tissues in the insect body. Thus respiratory gases diffuse through air most of the way to and from every cell. The insect respiratory system communicates with the outside environment through gated openings called spiracles in the sides of the abdomen and thorax (**Figure 49.4A,B**). The spiracles open to allow gas exchange and then close to decrease water loss. They open into tubes called tracheae that branch into even finer tubes, or tracheoles, which end in tiny air capillaries that are the actual gas exchange surfaces (**Figure 49.4C**). In the insect's flight muscles and other highly active tissues, every mitochondrion is close to an air capillary.

Fish gills use countercurrent flow to maximize gas exchange

The internal gills of fishes are supported by gill arches that lie between the mouth cavity and the protective opercular flaps on

49.4 The Tracheal Gas Exchange System of Insects (A) In insects, respiratory gases diffuse through a system of air tubes (tracheae) that open to the external environment through holes called spiracles. (B) The spiracles of a hawkmoth larva run down its sides. (C) A scanning electron micrograph shows an insect trachea dividing into smaller tracheoles and still finer air capillaries.

Acherontia atropos

49.5 Fish Gills (A) Water flows unidirectionally over the gills of a fish. (B) Gill filaments have a large surface area and thin tissues. (C) Blood flows through the lamellae in the direction opposite (left to right, in this depiction; small blue and red arrows) to the flow of water (right to left; large blue arrows) over the lamellae.

the sides of the fish just behind the eyes (**Figure 49.5A**). Water flows unidirectionally into the fish's mouth, over the gills, and out from under the opercular flaps. Thus there is a constant one-way flow of oxygenated water over the gills, maximizing the P_{O_2} on the external gill surfaces. On the internal side of the gill membranes, the circulation of blood minimizes the P_{O_2} by sweeping O_2 away as rapidly as it diffuses across.

Gills have an enormous surface area for gas exchange because they are so highly divided. Each gill consists of hundreds of ribbonlike gill filaments (**Figure 49.5B**). The upper and lower flat surfaces of each gill filament are covered with rows of evenly spaced folds, or lamellae. The lamellae are the actual gas exchange surfaces. Because the lamellae are exceedingly thin, the path length (L) for diffusion of gases between blood and water is minimized. The surfaces of the lamellae consist of highly flattened epithelial cells, so the water and the fish's red blood cells are separated by little more than 1 to 2 micrometers.

The flow of blood perfusing the inner surfaces of the lamellae, like the flow of water over the gills, is unidirectional. **Afferent** blood vessels bring deoxygenated blood to the gills, while **efferent** blood vessels take oxygenated blood away from the gills (**Figure 49.5C**). Blood flows through the lamellae in the direction opposite to the flow of water over the lamellae. This **countercurrent flow** optimizes the P_{O_2} gradient between water and blood, making gas exchange more efficient than it would be in a system using concurrent (parallel) flow (**Figure 49.6**).

Some fishes, including anchovies, tuna, and certain sharks, ventilate their gills by swimming almost constantly with their mouths open. Most fishes, however, ventilate their gills by means of a two-pump mechanism. The closing and contracting of the mouth cavity pushes water over the gills, and the expansion of the opercular cavity prior to opening of the opercular flaps pulls water over the gills.

These adaptations for maximizing the surface area (A) for diffusion, minimizing the path length (L) for diffusion, and maximizing the P_{O_2} gradient allow fishes to extract an adequate supply of O_2 from meager environmental sources.

Birds use unidirectional ventilation to maximize gas exchange

Birds are remarkable for their ability to sustain high levels of activity for a long time—for example, on long-distance flights—even at high altitudes where mammals cannot even survive. The first team to climb Mount Everest (8,850 m) was surprised to see birds flying over the mountain when they themselves could barely move without supplemental O_2 . Bar-headed geese regularly migrate over Mt. Everest and surrounding peaks, but the highest recorded flight of a bird is from a Ruppell's griffon, a vulture, that was sucked into a jet engine at 11,278 m.

(A) Concurrent flow

(B) Countercurrent flow

49.6 Countercurrent Flow Enables More Complete Exchange

In these models of concurrent and countercurrent gas exchange, the numbers represent the O₂ saturation percentages of blood and water. (A) In a concurrent exchanger, the saturation percentages of blood and water reach equilibrium halfway across the exchange surface. (B) A countercurrent exchanger allows more complete gas exchange because the water is always more O₂-saturated than the blood; thus a gradient of O₂ saturation is maintained.

Humans cannot survive at such altitudes without supplemental O₂. Yet the lungs of a bird are smaller than the lungs of a similar-sized mammal, and bird lungs expand and contract less during a breathing cycle than do mammalian lungs. Furthermore, bird lungs *are compressed* during inhalation and *expand* during exhalation. How do birds accomplish such remarkable feats of respiratory gas exchange?

The structure of bird lungs allows air to flow unidirectionally through the lungs, rather than bidirectionally through all the same airways, as it does in mammals. Because mammalian lungs are never completely emptied of air during exhalation, there is always some lung volume that is not ventilated with fresh air. The air remaining in lungs and airways after exhalation is called **dead space**. Bird lungs, by contrast, have very little dead space, and the fresh incoming air is not mixed with stale air. In this way, a high P_{O₂} gradient is maintained.

An important and unique feature of the avian respiratory system is its **air sacs**, which occupy much of the body cavity of the bird (Figure 49.7A). The air sacs are interconnected with each other, with the lungs, and with air spaces in some of the bones. The air sacs receive inhaled air, but they are not gas exchange surfaces; they are integrally involved, however, in the flow of air through the lungs. As in other air-breathing vertebrates, air enters and leaves a bird's gas exchange system through the **trachea** (commonly known as the windpipe, and not to be confused with the air-conducting tracheae of insects) (Figure 49.7B). The trachea divides into two smaller airways, the **primary bronchi** (singular *bronchus*). The primary bronchi extend all the way to the posterior air sacs and branch into **secondary bronchi**. The posterior air sacs also have connections to

(A) Avian air sacs and lungs

(B) Diagram of respiratory system

49.7 The Respiratory System of a Bird (A) Air sacs and air spaces in the bones are unique to birds. (B) The lung is divided into numerous parabronchi. Primary and secondary bronchi connect the lung to the air sacs. (C) Air flows through bird lungs unidirectionally in parabronchi. Air capillaries, the site of gas exchange, branch off the parabronchi.

the secondary bronchi. Secondary bronchi divide into tubelike **parabronchi** that run parallel to one another through the lungs.

Branching off the parabronchi are numerous tiny air capillaries (Figure 49.7C). Air flows through the parabronchi and diffuses into the air capillaries, which are the gas exchange surfaces. They are so numerous that they provide an enormous surface area for gas exchange. The parabronchi coalesce into larger bronchi that take the air out of the lungs and into anterior air sacs and back to the trachea. Thus the anatomy of a bird's airways allows air to flow unidirectionally through the lungs: trachea, bronchi, posterior air sacs, parabronchi, anterior air sacs, trachea.

49.8 The Path of Air Flow through Bird Lungs The air a bird takes in by breathing (blue) travels through the lungs in one direction, from the posterior to the anterior air sacs. Each breath of air remains in the system for two breathing cycles.

The puzzle of how birds breathe was solved by placing small O_2 electronic sensors at different locations in birds' air sacs and airways. The birds were then exposed to pure O_2 for just a single breath, which made it possible to track that particular inhalation. The experiment demonstrated that a single breath remains in a bird's gas exchange system for two cycles of inhalation and exhalation, and that the air sacs work like bellows; inhalation expands the sacs, and exhalation compresses them to maintain a continuous, unidirectional flow of fresh air through the lungs (Figure 49.8).

The advantages of the bird gas exchange system are similar to those of fish gills. The air sacs keep fresh air flowing unidirectionally over the gas exchange surfaces without interruption. Thus a bird can supply its gas exchange surfaces with a continuous flow of fresh air that has a P_{O_2} very close to that of the ambient air. Even when the P_{O_2} of the ambient air is only slightly above that of the blood, O_2 can diffuse from air to blood.

Tidal ventilation produces dead space that limits gas exchange efficiency

Lungs evolved in early lungfish as outpocketings of the digestive tract. Although their structure has evolved considerably, lungs remain dead-end sacs in all air-breathing vertebrates except birds (and likely their extinct reptilian ancestors). Because of this, ventilation cannot be constant and unidirectional but must be **tidal**: air flows in and exhaled gases flow out by the same route. Since the lungs and airways can never be completely emptied of air, they always contain dead space. We can easily measure the

Go to Animated Tutorial 49.1
Airflow in Birds
Life10e.com/at49.1

volumes of air exchanged during breathing, but we have to use an indirect method to measure the dead space contained in the lungs and airways. Measures of dead space are important in assessing lung health and disease.

A spirometer is a device that measures the volume of air breathed in and out (Figure 49.9). Using a human as an example, the amount of air that moves in and out per breath when at rest is called the **tidal volume (TV)** (about 500 ml for an average human adult). When we breathe in as much as possible,

RESEARCHTOOLS

49.9 Measuring Lung Ventilation A spirometer is a device that measures the volume of air a person breathes through a mouthpiece. The combined tidal volume, inspiratory reserve volume, and expiratory reserve volume are the lungs' vital capacity.

the additional volume is the **inspiratory reserve volume (IRV)**. Conversely, if we forcefully exhale as much air as possible, the additional amount of air expelled is the **expiratory reserve volume (ERV)**. The maximum capacity for air exchange in one breath, or the **vital capacity (VC)**, is the sum of TV + IRV + ERV. The vital capacity of an athlete is generally greater than that of a nonathlete, and vital capacity decreases with age because of stiffening of the lung tissue.

Vital capacity is not the entire lung capacity because of the dead space, also called the **residual volume (RV)**. We can't measure RV directly with the spirometer, but we can measure it indirectly using the helium dilution method. Briefly, a person breathes from a closed reservoir with a known volume of air containing a known amount of helium (He). The helium is not absorbed from the lungs, so it becomes evenly distributed between the lungs and the reservoir as the subject inhales and exhales. Because the fixed amount of He becomes dispersed in a larger volume of air, its concentration decreases. That decrease in He concentration enables us to calculate the subject's **functional residual volume (FRV)**, which is the ERV + RV. Since we *can* measure the ERV with the spirometer, we can subtract the ERV from the FRV to obtain the RV.

Why is the RV important? Referring to Figure 49.9, you will see that for a normal person the ERV is about 1,000 ml and the RV is 1,000 ml. Thus the FRV is 2,000 ml, but the tidal volume is only 500 ml; this means that the air that reaches the alveoli (the actual gas exchange surfaces) with each breath consists of only 500 ml of fresh air diluted by 2,000 ml of stale air. The maximum P_{O_2} in this mixed air is much below the P_{O_2} of the outside air, and because of the tidal ventilation pattern, the P_{O_2} in the alveoli is steadily dropping during the breathing cycle. The RV is important because it contributes to the FRC and to the dilution of the O_2 in the inhaled air. Any disease or condition that increases the RV (such as emphysema or pulmonary fibrosis) compromises a patient's respiratory ability. Similarly, considering the mixing of fresh air with the FRV, you can understand why reductions in tidal volume can be a problem—and therefore why patients recovering from surgery are encouraged to breathe deeply, even if it hurts.

Offsetting the inefficiencies of tidal breathing, mammalian lungs have some design features to maximize the rate of gas exchange: an enormous surface area and a very short path length for diffusion.

RECAP 49.2

The major adaptations that increase animals' efficiency of respiratory gas exchange are a large surface area for exchange and a maximized partial pressure gradient across that surface.

- Describe three different ways that the partial pressure gradient for O_2 exchange is maximized across fish gills. [See pp. 1009–1010 and Figures 49.5 and 49.6](#)
- What respiratory adaptations enable birds to fly at extremely high altitudes? [See pp. 1010–1011 and Figures 49.7 and 49.8](#)
- Explain why residual volume limits the efficiency of tidal breathing. [See pp. 1012–1013 and Figure 49.9](#)

Despite their limitations, mammalian lungs serve the respiratory needs of mammals, including humans, well. Next we will look at the human respiratory system as an example.

49.3 How Do Human Lungs Work?

Air enters the lungs through the oral cavity or through the nasal passage, which join together in the **pharynx** ([Figure 49.10A](#)). Below the pharynx, the esophagus conducts food to the stomach, and the trachea conducts air to the lungs. At the beginning of this airway is the **larynx**, or voice box, which houses the vocal cords. The larynx is the lump that you can see or feel on the front of your neck. The trachea is about 2 centimeters in diameter. C-shaped bands of cartilage prevent the thin walls of the trachea from collapsing as air pressure changes during the breathing cycle. If you run your fingers down the front of your neck just below your larynx, you can feel a few of these bands of cartilage.

The trachea branches into two bronchi, one leading to each lung. The bronchi branch repeatedly to generate a treelike structure of progressively smaller airways extending to all regions of the lungs. After four branchings, the cartilage supports disappear, marking the transition to **bronchioles**. After about 16 branchings, the bronchioles are less than a millimeter in diameter, and tiny, thin-walled air sacs called **alveoli** begin to appear. Alveoli are the sites of gas exchange. After the first alveoli there are about six more branchings of the airways that end in clusters of alveoli ([Figure 49.10B](#)). Because the airways conduct air only to and from the alveoli and do not themselves participate in gas exchange, their volume is dead space.

Human lungs have about 300 million alveoli. Although each alveolus is very small, their combined surface area for diffusion of respiratory gases is about 70 square meters—about one-fourth the size of a basketball court. Each alveolus is made of very thin cells. Between and surrounding the alveoli are networks of capillaries whose walls are also very thin. Thus where capillary meets alveolus, the length of the diffusion path between air and blood is less than 2 micrometers ([Figure 49.10C](#)).

Diseases of the bronchioles and alveoli are the third leading cause of death in the United States as of 2010. Among these diseases, the most lethal is emphysema, a condition in which inflammation damages and eventually destroys the walls of the alveoli. As a result, the lungs have fewer but larger alveoli, the RV increases, and the lungs lose elasticity. Although genetic factors can contribute to emphysema, the principal cause of the disease is smoking.

Respiratory tract secretions aid ventilation

Mammalian lungs produce two secretions that do not directly influence their gas exchange but do affect the process of ventilation: mucus and surfactant.

Many cells lining the airways produce sticky mucus that captures bits of dirt and microorganisms that are inhaled. Other cells lining the airways have cilia whose beating continually sweeps the mucus, with its trapped debris, up toward the

pharynx, where it can be swallowed or spit out. This phenomenon, called the mucus escalator, can be adversely affected by inhaled pollutants. Smoking one cigarette can immobilize the cilia of the airways for hours. A smoker's cough results from the need to clear the obstructing mucus from the airways when the mucus escalator is out of order.

A **surfactant** is a substance that reduces the surface tension of a liquid. **Surface tension** gives the surface of a liquid the properties of an elastic membrane, and it is why certain insects, such as water-striders, can walk on water. As discussed in Section 2.4, surface tension is the result of chemical forces of attraction between water molecules. The attractive forces working on the water molecules at the surface pull from below and from the sides but not from above. This imbalance of forces creates surface tension. The thin film of fluid covering the air-facing surfaces of the alveoli has surface tension that contributes to the lungs' elasticity. To inflate the lungs, enough force has to be generated to overcome both the elasticity of the lung tissue and the surface tension in the alveoli.

Lung surfactant is a fatty, detergent-like substance that is critical for reducing the work necessary to inflate the lungs. Certain cells in the alveoli release surfactant molecules when they are stretched. If a baby is born more than a month prematurely, these cells may not have developed the ability to produce surfactant. A baby with this condition, known as respiratory distress syndrome, will have great difficulty breathing and may die from exhaustion and lack of O_2 . Common treatments for premature babies have been to put them on respirators to assist their breathing and to give them hormones to speed lung

development. A newer approach is to apply surfactant to the lungs via an aerosol.

Lungs are ventilated by pressure changes in the thoracic cavity

Human lungs are suspended in the **thoracic cavity**, a closed compartment bounded on the bottom by a sheet of muscle called the **diaphragm** (see Figure 49.10A). Each lung is covered by a continuous sheet of tissue called the **pleural membrane** that also lines the thoracic cavity adjacent to that lung. There is no real space between the pleural membranes of the lung and the thoracic cavity, but there is a thin film of fluid. This fluid lubricates the inner surfaces of the pleural membranes so they can slip and slide against each other. Just as we mentioned above in the explanation of surface tension, there are forces of attraction between the molecules of fluid in the pleural membranes. As a result, it is difficult to pull the pleural membranes apart. Think of two wet panes of glass or two wet microscope slides; you can slide them past each other, but it is difficult to separate them. While the inner surfaces of the pleural membranes are "stuck" to each other by surface tension, they can move relative to each other during breathing movements.

Inhalation and exhalation involve changes in the volume of the thoracic cavity (Figure 49.11). Because the pleural membranes covering the cavity wall and the lung surface are stuck to each other by surface tension, any attempt to increase the volume of the thoracic cavity increases the tension between the pleural membranes. Even between breaths, there is tension between the pleural membranes because the rib cage is

pulling outward and the elasticity of the lung tissue is pulling inward. This slight negative pressure keeps the alveoli partly inflated even at the end of an exhalation. If the thoracic cavity is punctured—by a knife wound, for example—air can leak into the space between the pleural membranes and cause the lung to deflate. If the wound is not sealed, breathing movements pull air in between the pleural membranes rather than into the lung (a “sucking chest wound”), and there is no ventilation of the alveoli in that lung—a condition called “collapsed lung.”

At rest, inhalation is initiated by contraction of the muscular diaphragm (see Figure 49.11A). As the domed diaphragm contracts, it pulls down, expanding the thoracic cavity and pulling on the pleural membranes. Since the pleural membranes cannot separate, they pull on the lungs; air rushes in through the trachea from the outside and the lungs expand. Exhalation begins when contraction of the diaphragm ceases. As the diaphragm relaxes, the elastic recoil of the lung tissues pulls the diaphragm up and pushes air out through the airways (see Figure 49.11B). When a person is at rest, inhalation is an active process and exhalation is a passive process.

The diaphragm is not the only muscle that can change the volume of the thoracic cavity. Between the ribs are two sets of **intercostal muscles**. The external intercostal muscles expand the thoracic cavity by lifting the ribs up and outward. The internal intercostal muscles decrease the volume of the thoracic cavity by pulling the ribs down and inward. During strenuous exercise, the external intercostal muscles increase the volume of air inhaled, making use of the inspiratory reserve volume, and the internal intercostal muscles increase the amount of air exhaled, making use of the expiratory reserve volume. The abdominal muscles can also aid in breathing. When they contract, they cause the abdominal contents to push up on the diaphragm and thereby contribute to the expiratory reserve volume.

Remember that ventilation and perfusion work together to maximize the partial pressure gradients across the alveolar membranes. Ventilation delivers O_2 to the environmental side of the exchange surface, where it diffuses across and is swept away by the perfusing blood, which carries it to the tissues. The reverse is true for CO_2 . Perfusion delivers CO_2 to the exchange surface, where it diffuses and is swept away by ventilation.

RECAP 49.3

The mammalian respiratory system consists of a highly branching system of airways that lead to alveoli—the gas exchange surfaces. Respiratory muscles ventilate the alveoli by creating pressure differences between the lungs and the outside air. CO_2 and O_2 are exchanged across thin capillary and alveoli walls by diffusion.

- Describe the path that a breath of air takes from the nose to the gas exchange surfaces. **See p. 1013 and Figure 49.10**
- What roles do mucus and surfactant play in maintaining the function of the mammalian respiratory system? **See pp. 1013 and 1015**
- Explain the anatomical and functional relationships between the thoracic cavity, the pleural membranes, and the lungs. **See pp. 1015–1016 and Figure 49.11**

Having discussed how respiratory gases get to and from the environmental side of the gas exchange membranes through ventilation, we will now look at how these gases get to and from the internal side of those membranes through perfusion.

49.4

How Does Blood Transport Respiratory Gases?

Perfusion of the lungs is one of the functions of the circulatory system. The circulatory system uses a pump (the heart) and a network of vessels to transport blood around the body. Circulatory systems are the subject of Chapter 50, so here we will discuss only one aspect of perfusion: how blood transports respiratory gases.

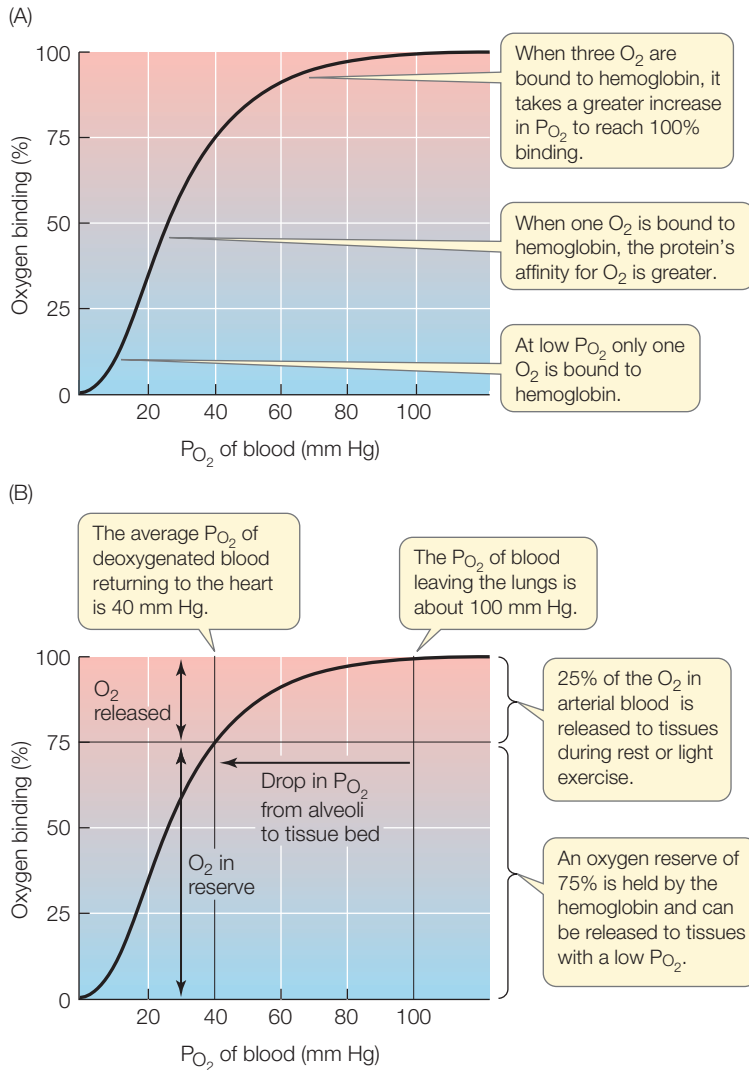

The liquid part of blood, the plasma, carries some O_2 in solution, but its ability to transport this nonpolar molecule is limited. The blood plasma of a human can contain in solution only about 0.3 ml of O_2 per 100 ml of plasma, which is inadequate to support even basal metabolism. However, the blood of most animals, vertebrate and invertebrate, contains molecules that bind and release O_2 and thus augment its transport capacity. These molecules pick up O_2 where P_{O_2} is high and release it where P_{O_2} is lower. There are many O_2 transport molecules in the animal kingdom, but in vertebrates this role is played by hemoglobin, a protein contained in red blood cells. Hemoglobin increases the capacity of blood to carry 60 times more oxygen than it could carry in solution, making high rates of metabolism possible.

Hemoglobin combines reversibly with O_2

Red blood cells contain enormous numbers of hemoglobin molecules. **Hemoglobin** is a protein consisting of four polypeptide subunits (see Figure 3.11), each of which surrounds a heme group—an iron-containing ring structure that can reversibly bind a molecule of O_2 . Thus each hemoglobin molecule can bind and release up to four O_2 molecules, enabling the blood to carry a large amount of O_2 to the body's tissues.

Hemoglobin's ability to pick up or release O_2 depends on the P_{O_2} in its environment. When the P_{O_2} of the blood plasma is high, as it usually is in the lung capillaries, each hemoglobin molecule can carry its maximum load of four O_2 molecules. As the blood circulates through the rest of the body, it releases some of the O_2 it is carrying when it encounters lower P_{O_2} values in the body's tissues.

The relationship between P_{O_2} and the amount of O_2 bound to hemoglobin is not linear but S-shaped (sigmoidal). The hemoglobin-oxygen binding curve reflects interactions between the four subunits of the hemoglobin molecule. At low P_{O_2} values, only one subunit will bind an O_2 molecule (**Figure 49.12A**). When it does so, the shape of that subunit changes, altering the quaternary structure of the entire hemoglobin molecule. That structural change makes it easier for the other subunits to bind an O_2 molecule; that is, their O_2 *affinity* is increased. Therefore a smaller increase in P_{O_2} is necessary to get the hemoglobin molecules to bind a second O_2 molecule (that is, to become

49.12 Binding of O_2 to Hemoglobin Depends on P_{O_2} (A) The sigmoidal shape of hemoglobin's oxygen binding curve reflects positive cooperativity among hemoglobin's subunits. (B) Hemoglobin in blood leaving the lungs is 100 percent saturated (four O_2 molecules are bound to each hemoglobin molecule). Most hemoglobin molecules drop only one of their four O_2 molecules as they circulate through the body and are still 75 percent saturated when the blood returns to the lungs. The steep portion of this O_2 -binding curve comes into play when tissue P_{O_2} falls below the normal 40 mm Hg, at which point hemoglobin "unloads" its O_2 reserves.

50% saturated) than was necessary to get them to bind one O_2 molecule (to become 25% saturated). This change in affinity is reflected in the increased steepness of the O_2 binding curve. The influence of O_2 binding by one subunit on the O_2 affinity of the other subunits is called **positive cooperativity**.

Once the third O_2 molecule is bound, the relationship seems to change, as a larger increase in P_{O_2} is required for the hemoglobin to reach 100 percent saturation. This upper bend of the sigmoid curve is due to a probability phenomenon. The closer we get to having all subunits occupied, the less likely it is that any particular O_2 molecule will find a place to bind. Therefore it takes a relatively greater P_{O_2} to achieve 100 percent saturation.

The O_2 -binding/dissociation properties of hemoglobin help get O_2 to the tissues that need it most (Figure 49.12B). In the

lungs, where the P_{O_2} is about 100 mm Hg, hemoglobin is 100 percent saturated. The P_{O_2} in blood returning to the heart from the body (at rest) is usually about 40 mm Hg. You can see that at this P_{O_2} the hemoglobin is still about 75 percent saturated. This means that as the blood circulates around the body, it releases only about one in four of the O_2 molecules it carries. This system seems inefficient, but it is really quite adaptive, because the hemoglobin keeps 75 percent of its O_2 in reserve to meet peak demands of highly active tissues.

When a tissue becomes starved of O_2 and its local P_{O_2} falls below 40 mm Hg, the hemoglobin flowing through that tissue is on the steep portion of its binding/dissociation curve. That means relatively small decreases in P_{O_2} below 40 mm Hg will result in the release of lots of O_2 to the tissue. Thus hemoglobin is very effective in making O_2 available to tissues precisely when and where it is needed most.

The O_2 transport function of hemoglobin can rapidly and tragically be disrupted by a common by-product of incomplete combustion: carbon monoxide (CO). If CO from a faulty heating system, engine exhaust, or burning charcoal accumulates in a closed space, the results can be deadly. Because CO binds to hemoglobin with a 240-fold higher affinity than O_2 , it prevents hemoglobin from transporting O_2 . In the United States, more than 5,000 people die each year from CO poisoning.

Hemoglobin: Loading and Unloading
[Life10e.com/at49.3](https://www.life10e.com/at49.3)

Myoglobin holds an O_2 reserve

Muscle cells have their own O_2 -binding molecule, **myoglobin**. Myoglobin consists of just one polypeptide chain associated with an iron-containing ring structure that can bind one O_2 molecule (see Figure 24.11). Myoglobin has a higher affinity for O_2 than hemoglobin does, so it picks up and holds O_2 at P_{O_2} values at which hemoglobin is releasing its bound O_2 (Figure 49.13).

Myoglobin facilitates the diffusion of O_2 in muscle cells and provides an O_2 reserve for times when metabolic demands are high and blood flow is interrupted. Interruption of blood flow in muscles is common because contracting muscles squeeze blood vessels. When tissue P_{O_2} values are low and hemoglobin can no longer supply more O_2 , myoglobin releases its bound O_2 . Diving mammals such as seals have high concentrations of myoglobin in their muscles, which is one reason they can stay under water for so long. (We will discuss more adaptations for diving in Chapter 50.) Even in non-diving animals, muscles called on for extended periods of work frequently have more myoglobin than muscles that are used for short, intermittent periods, as noted in Section 48.2.

Hemoglobin's affinity for O_2 is variable

Various factors influence the O_2 -binding/dissociation properties of hemoglobin, thereby influencing O_2 delivery to tissues. Three of these factors are the chemical composition of the hemoglobin, the blood pH, and the presence of 2,3-bisphosphoglyceric acid (BPG) in red blood cells.

49.13 Oxygen-Binding Adaptations Myoglobin and the different hemoglobins have different O_2 -binding properties adapted to different circumstances. Fetal hemoglobin, for example, has a higher affinity for O_2 than does adult hemoglobin, facilitating O_2 transfer in the placenta. When high metabolism lowers the pH of the blood, or low O_2 increases bisphosphoglyceric acid (BPG), hemoglobin releases more of its O_2 .

Go to Activity 49.2 Oxygen-Binding Curves
Life10e.com/ac49.2

HEMOGLOBIN COMPOSITION There is more than one type of hemoglobin, because the chemical composition of the polypeptide chains that form the hemoglobin molecule varies. The normal hemoglobin of adult humans has two each of two kinds of polypeptide chains—two α -globin chains and two β -globin chains. This normal adult hemoglobin has the O_2 -binding characteristics shown in **Figure 49.13**.

Before birth, the human fetus has a different form of hemoglobin, consisting of two α -globin and two γ -globin chains. The functional difference between fetal and adult hemoglobin is that fetal hemoglobin has a higher affinity for O_2 . Therefore the fetal hemoglobin–oxygen binding/dissociation curve is shifted to the left compared with the adult curve (see **Figure 49.13**). You can see from these curves that if both types of hemoglobin are at the same P_{O_2} (as they are in the placenta), fetal hemoglobin will pick up O_2 that the adult hemoglobin releases. This difference in O_2 affinities enables the efficient transfer of O_2 from the mother's blood to the fetus's blood.

HEMOGLOBIN AND PH The O_2 -binding properties of hemoglobin are also influenced by physiological conditions. The influence of pH (hydrogen ion concentration) on the function of hemoglobin is known as the **Bohr effect**. As blood passes through metabolically active tissue such as exercising muscle, it picks up acidic metabolites such as lactic acid, fatty acids, and CO_2 . As a result, blood pH falls. The excess H^+ binds preferentially to deoxygenated hemoglobin and decreases its affinity for O_2 and the O_2 -binding/dissociation curve of hemoglobin shifts to the right (see **Figure 49.13**). This shift means the hemoglobin will release more O_2 in tissues where pH is low—another way that O_2 is supplied where and when it is most needed.

2,3-BISPHOSPHOGLYCERIC ACID BPG is a metabolite of glycolysis. Mammalian red blood cells respond to low P_{O_2} by increasing their rate of glycolysis and thus producing more BPG, which is an important regulator of hemoglobin function. BPG, like excess H^+ , reversibly combines with *deoxygenated* hemoglobin and lowers its affinity for O_2 . The result is that at any P_{O_2} , hemoglobin releases more of its bound O_2 than it otherwise would. In other words, BPG shifts the O_2 -binding/dissociation curve of mammalian hemoglobin to the right.

When humans go to high altitudes, or when they cease being sedentary and begin to exercise, their red blood cells are exposed to a lower P_{O_2} and their level of BPG goes up, making it easier for hemoglobin to deliver more O_2 to tissues. The reason fetal hemoglobin has a left-shifted O_2 -binding/dissociation curve is that its γ -globin chains have a lower affinity for BPG than do the β -globin chains of adult hemoglobin.

CO_2 is transported as bicarbonate ions in the blood

Delivering O_2 to tissues is only half the respiratory function of blood. Blood also must take CO_2 , a metabolic waste product, away from tissues (**Figure 49.14**). CO_2 is highly soluble and readily diffuses through cell membranes, moving from its site of production in the tissues into the blood, where the partial pressure of CO_2 (P_{CO_2}) is lower. However, very little dissolved CO_2 is transported by the blood. Most CO_2 produced by the tissues is transported to the lungs in the form of bicarbonate ions, HCO_3^- . CO_2 is converted to HCO_3^- , transported to the lungs, and then converted back to CO_2 in several steps.

When CO_2 dissolves in water, some of it slowly reacts with the water molecules to form carbonic acid (H_2CO_3), some of which then dissociates into a proton (H^+) and a bicarbonate ion (HCO_3^-). This reversible reaction is expressed as follows:

In the extracellular fluid, the reaction between CO_2 and H_2O proceeds slowly. But it is a different story in the endothelial cells of the capillaries and in the red blood cells, where the enzyme carbonic anhydrase speeds up the conversion of CO_2 to H_2CO_3 . The newly formed H_2CO_3 dissociates, and the resulting bicarbonate ions enter the plasma in exchange for Cl^- (see **Figure 49.14**). By converting CO_2 to H_2CO_3 , carbonic anhydrase reduces the P_{CO_2} in these cells and in the plasma, facilitating the diffusion of CO_2 from tissue cells to endothelial cells, plasma, and red blood cells. Some CO_2 is also carried in chemical combination with hemoglobin.

In the lungs, the reactions involving CO_2 and bicarbonate ions are reversed. Remember that an enzyme such as carbonic anhydrase only speeds up a reversible reaction; it does not determine its direction. The direction is determined by concentrations of reactants and products. Ventilation keeps the P_{CO_2} in the alveoli low, so CO_2 diffuses from the blood plasma into the alveoli, lowering the P_{CO_2} in the blood, which favors the conversion of HCO_3^- into CO_2 .

49.14 Carbon Dioxide Is Transported as Bicarbonate Ions
Carbonic anhydrase (CA) in capillary endothelial cells and in red blood cells facilitates conversion of CO_2 produced by tissues into

bicarbonate ions carried by the plasma. In the lungs, the process is reversed as CO_2 is exhaled.

RECAP 49.4

O_2 is transported from the lungs to the body's tissues in reversible combination with hemoglobin. Each hemoglobin molecule can reversibly combine with four O_2 molecules; the percent saturation of the binding sites is a function of the P_{O_2} in the hemoglobin's environment.

- Explain the advantage of having hemoglobin hold on to three O_2 molecules at the usual P_{O_2} of mixed venous blood. **See pp. 1016–1017 and Figure 49.12**
- How is the O_2 -binding/dissociation curve of hemoglobin influenced by pH? By BPG? By development from fetus to newborn infant? **See p. 1018 and Figure 49.13**
- How is CO_2 transported in the blood? **See p. 1018 and Figure 49.14**

We must breathe every minute of our lives, but most of us usually don't worry about it, or even think about it very often. In the next section we will examine how the regular breathing cycle is generated and controlled by the central nervous system.

49.5 How Is Breathing Regulated?

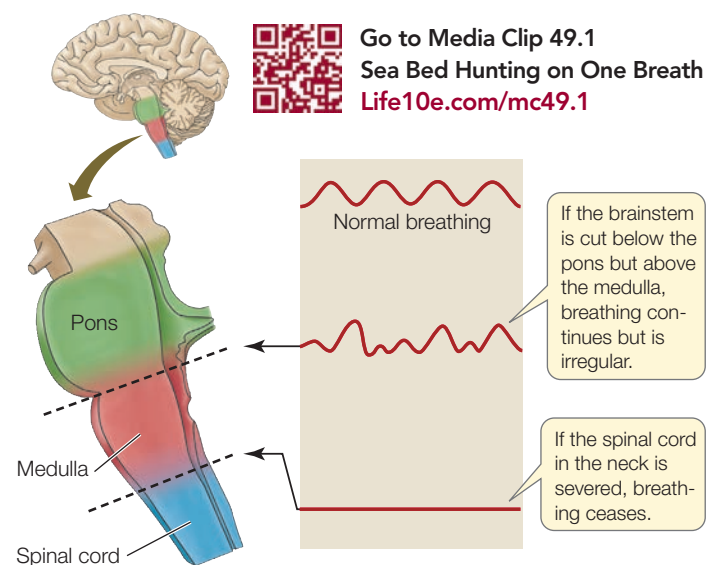

Breathing is an involuntary function of the central nervous system. The breathing pattern easily adjusts itself around other activities (such as speech and eating), and breathing rates change to match the metabolic demands of our bodies. How is this accomplished?

Breathing is controlled in the brainstem

The basic breathing rhythm is an involuntary function driven by a rhythm-generating neural circuit in the brainstem. Breathing is also under voluntary control that enables activities such as talking, singing, sighing, and breath-hold diving. Voluntary control of breathing is eventually and inevitably overridden by feedback

information that conveys the body's need for an adequate O_2 supply and CO_2 elimination.

Breathing ceases if the spinal cord is severed in the neck region, showing that breathing is generated in the brain. If the brainstem is cut just above the medulla (the segment of the brainstem just above the spinal cord), an irregular breathing pattern remains (Figure 49.15). A group of respiratory motor neurons in the dorsal medulla increase their firing rates just before an inhalation begins. The axons of these neurons leave the CNS in the neck region to form the phrenic nerve, which innervates the diaphragm. As more and more of these neurons fire—and fire faster and faster—the diaphragm contracts. All of a sudden the neurons stop firing, the diaphragm relaxes, and

49.15 Breathing Is Controlled in the Brainstem Basic breathing rhythm is generated in the medulla and is modified by neurons in or above the pons.

49.16 Carbon Dioxide Affects Breathing Rate The breathing mechanism is more sensitive to increased levels of CO_2 in arterial blood than to decreased amounts of O_2 .

exhalation begins. Exhalation is usually a passive process that depends on the elastic recoil of the lung tissues. Another group of respiratory motor neurons in the ventral medulla becomes active when breathing demand is high. These motor neurons communicate through thoracic spinal nerves to the intercostal muscles. By expanding and contracting the rib cage, the intercostal muscles increase both the inhalation and the exhalation volumes.

Neurons in the lower region of the pons help regularize the basic respiratory rhythm. Still higher brain areas modify breathing to accommodate speech, ingestion of food, coughing, and emotional states.

Regulating breathing requires feedback

When breathing or metabolism changes, it alters the P_{O_2} and P_{CO_2} in the blood. We should therefore expect the blood levels of one or both of these gases to provide feedback information to the breathing rhythm generator in the medulla. Humans and other mammals are remarkably insensitive to falling levels of O_2 in arterial blood but are extremely sensitive to increases in CO_2 . That is, arterial P_{O_2} can deviate considerably from normal without causing much of an increase in ventilation rate, but even a small rise in arterial P_{CO_2} causes a large increase in ventilation (Figure 49.16). This relationship is reversed for water-breathing animals, in which O_2 is the primary feedback stimulus for gill ventilation.

We might ask whether it is an increase in the P_{CO_2} of the blood that stimulates increased breathing when we exercise. To answer this question, C. R. Bainton observed dogs running on treadmills at different inclines (Figure 49.17). As the incline of the treadmill gradually increased, the dogs ran at the same speed but were working harder because they were running uphill. The P_{CO_2} of their blood increased as the incline of the

INVESTIGATINGLIFE

49.17 The Respiratory Control System Is Sensitive to P_{CO_2}

What is the metabolic feedback signal that controls ventilation rate

during exercise? To find out, Cedric Bainton conducted a series of experiments with dogs trained to run on treadmills.^a

HYPOTHESIS Rising levels of blood CO_2 during exercise is the feedback signal that stimulates an increase in respiratory rate.

Method

1. Dogs are trained to run on a treadmill.
2. The dogs are equipped with instruments that measure respiratory rate and with arterial catheters that enable sampling of blood.
3. As a dog runs, the incline of the treadmill is changed to gradually increase the metabolic workload.
4. Ventilation rate (V ; L/min) is plotted as a function of arterial P_{CO_2} (mm Hg).

Results

When the workload is altered by slowly changing the incline of the treadmill (no change in speed), the ventilation rate is a function of P_{CO_2} .

CONCLUSION CO_2 level in arterial blood is the metabolic feedback signal that regulates respiration in response to workload.

^aBainton, C. R. 1972. *Journal of Applied Physiology* 33: 778–787.

The Respiratory Control System Is Not Always Regulated by P_{CO_2}

Original Paper

Bainton, C. R. 1972. Effect of speed vs. grade and shivering on ventilation in dogs during active exercise. *Journal of Applied Physiology* 33: 778–787.

Analyze the Data

Experiments in which dogs run at different speeds while their P_{CO_2} and V are measured produce results different from those shown in Figure 49.17. When subjects run at different speeds, their P_{CO_2} s are the same and yet their V changes. To resolve the differences between these types of experiments, Bainton recorded P_{CO_2} and V in dogs, breath-by-breath immediately after a change in treadmill speed from 3 to 6 mph. The results for one experiment are shown in the table. When this dog was running at 3 mph, its average P_{CO_2} was 39 mm Hg and its V was 9 L/min. After the dog had run at 6 mph for a few minutes its average P_{CO_2} was 41 mm Hg and its V was 15.

QUESTION 1

Draw a plot with V on the y-axis and P_{CO_2} on the x-axis that shows the average values at 3 mph and 6 mph and also the breath-by-breath values (in the table) for the transition. Do the data support the hypothesis that P_{CO_2} is the feedback signal controlling ventilation rate? Why or why not?

QUESTION 2

How do you explain the average values after the dog had been running at the higher speed for a few minutes?

QUESTION 3

Relate these results to those obtained in the experiment in which the incline of the treadmill was gradually raised and lowered. Explain the differences between the results in terms of the P_{CO_2} sensing mechanism (Hint: use the concept of “set point” in your explanation).

Breath	P_{CO_2} (mm Hg)	V (L/min)
1	38.0	13.0
2	37.0	14.0
3	36.5	11.2
4	37.2	11.2
5	37.2	12.0
6	36.8	13.0
7	37.2	13.0

Go to **BioPortal** for all **WORKING WITH DATA** exercises

treadmill and respiratory gas exchange rate increased. Bainton observed a similar relationship between blood P_{CO_2} and respiratory rate as he lowered the treadmill back to its original position. These results indicated that blood P_{CO_2} could act as a signal to regulate breathing rate.

Before concluding that blood P_{CO_2} is the *only* signal that controls breathing rate, Bainton changed the experiment. Instead of increasing the incline of the treadmill, he increased its speed (see the Working with Data exercise above). In this experiment the P_{CO_2} of the blood remained constant as treadmill speed increased and as the respiratory gas exchange rate increased. Bainton concluded that blood P_{CO_2} is the primary metabolic feedback information for breathing. However, when an animal starts to run or changes its running speed, additional feedback information from receptors in muscles and joints changes its sensitivity to CO_2 —an example of feedforward information. As noted in Section 40.1, feedforward information can change the sensitivity or the set point of a regulatory system.

Where are partial pressures of gases in the blood sensed? The major site of P_{CO_2} sensitivity is an area on the ventral surface of the medulla. The primary sensitivity of these chemosensitive cells is not to CO_2 , however. Rather, they are stimulated by H^+ ions. The H^+ ion concentration, or pH, in the environment of these cells is a direct reflection of the P_{CO_2} of the blood. When the P_{CO_2} of the blood is higher than that of the extracellular fluid in this area, CO_2 diffuses out of the blood. That CO_2 interacts with H_2O to form carbonic acid (H_2CO_3), which dissociates into H^+ ions and HCO_3^- ions (see Figure 49.14). The H^+ ions that are produced stimulate the chemosensitive cells that increase respiratory gas exchange. Thus even though we measure blood P_{CO_2} as the stimulus for breathing, the real stimulus is pH.

Sensitivity to blood P_{O_2} resides in nodes of neural tissue on the large blood vessels leaving the heart: the aorta and the carotid arteries (Figure 49.18). These **carotid bodies** and

49.18 Feedback Information Controls Breathing The body uses feedback information from chemosensors in the heart and brain to match breathing rate to metabolic demand.

aortic bodies are chemosensors. If the blood supply to these structures decreases, or if the blood P_{O_2} falls dramatically, the chemosensors are activated and send nerve impulses to the breathing control center. Although we are not very sensitive to changes in blood P_{O_2} , the carotid and aortic bodies can stimulate increases in breathing during exposure to very high altitudes or when blood volume or blood pressure is very low. Also, there is a synergism between CO_2 and O_2 sensing. When blood P_{CO_2} increases, there is an increased sensitivity to low O_2 , and vice versa.

RECAP 49.5

The rhythmic contractions of the respiratory muscles that drive breathing are generated by neurons in the brainstem.

- What is the primary chemical stimulus for controlling the respiratory rate, and where is it sensed? **See pp. 1019–1020 and Figures 49.16 and 49.18**
- Explain what feedforward information is and how exercise provides feedforward information in the respiratory control system. **See pp. 1020–1021 Figure 49.17**
- What are the functions of the carotid and aortic bodies? **See pp. 1021–1022 and Figure 49.18**

How do elephants avoid damage to the blood vessels of their thoracic cavities when they snorkel?

ANSWER

In all mammals except elephants, the surfaces of the lungs and the chest cavity move easily against each other. As the lungs inflate and deflate, their surface slips and slides against that of the chest cavity. In elephants, however, dense connective tissue attaches the surface of the lungs to the surface of the chest cavity. This connective tissue acts as reinforcement for the fragile

blood vessels on the surface of the chest cavity and prevents them from rupturing and filling the cavity with blood, which would destroy the function of the lungs—exchange of oxygen and carbon dioxide. The elephant is the only mammal that does not have a functional pleural space.

CHAPTER SUMMARY 49

49.1

What Physical Factors Govern Respiratory Gas Exchange?

- Most cells require a constant supply of O_2 and continuous removal of CO_2 . These **respiratory gases** are exchanged between an animal's body fluids and its environment by diffusion.
- **Fick's law of diffusion** shows how various physical factors influence the diffusion rate of gases. Adaptations to maximize respiratory gas exchange influence one or more variables of Fick's law.
- In water-breathing animals, gas exchange is limited by the low diffusion rate and low amount of O_2 in water. If water temperature rises, water-breathing animals face a double bind in that the amount of O_2 in water decreases, but their metabolism and the amount of work required to move water over the gas exchange surfaces increase. **Review Figure 49.2**
- In air, the **partial pressure** of oxygen (P_{O_2}) decreases with altitude.

49.2

What Adaptations Maximize Respiratory Gas Exchange?

- Adaptations to maximize gas exchange include increasing the surface area for gas exchange and maximizing partial pressure gradients across those exchange surfaces by ventilating the outer surface with the respiratory medium, and perfusing the inner surface with blood. **Review Figure 49.3**
- Insects distribute air throughout their bodies in a system of **tracheae**, tracheoles, and air capillaries. **Review Figure 49.4**
- The **gills** of fishes have large gas exchange surface areas that are ventilated continuously and unidirectionally with water. The **countercurrent flow** of blood helps increase the efficiency of gas exchange. **Review Figures 49.5, 49.6**

- The gas exchange system of birds includes **air sacs** that communicate with the lungs but are not used for gas exchange. Air flows unidirectionally through bird lungs; gases are exchanged in air capillaries that run between **parabronchi**. **Review Figure 49.7**
- Each breath of air remains in a bird's respiratory system for two breathing cycles. The air sacs work as bellows to supply the air capillaries with a continuous unidirectional flow of fresh air. **Review Figure 49.8, ANIMATED TUTORIAL 49.1**
- In all air-breathing vertebrates except birds, breathing is **tidal**. This is a less efficient form of gas exchange than that of fishes and birds. Although the volume of air exchanged with each breath can vary considerably in tidal breathing, the inhaled air is always mixed with stale air. **Review Figure 49.9**

49.3

How Do Human Lungs Work?

- In mammalian lungs, the gas exchange surface area provided by the millions of **alveoli** is enormous, and the diffusion path length between the air and perfusing blood is short. **Surface tension** in the alveoli would make inflation of the lungs difficult if the alveoli did not produce **surfactant**. **Review Figure 49.10, ACTIVITY 49.1**
- Inhalation occurs when contractions of the **diaphragm** increase volume and reduce pressure in the **thoracic cavity**, thereby pulling on the **pleural membranes**. Relaxation of the diaphragm increases pressure in the thoracic cavity and results in exhalation. **Review Figure 49.11, ANIMATED TUTORIAL 49.2**
- During periods of heavy metabolic demands such as strenuous exercise, the **intercostal muscles**, located between the ribs, increase the volume of air inhaled and exhaled.

continued

49.4 How Does Blood Transport Respiratory Gases?

- O_2 is reversibly bound to **hemoglobin** in red blood cells. Each hemoglobin molecule can carry a maximum of four O_2 molecules. Because of **positive cooperativity**, hemoglobin's affinity for O_2 depends on the P_{O_2} to which the hemoglobin is exposed. Therefore hemoglobin picks up O_2 as it flows through respiratory exchange structures and gives up O_2 in metabolically active tissues. **Review Figure 49.12, ANIMATED TUTORIAL 49.3**
- **Myoglobin** serves as an O_2 reserve in muscle.
- There is more than one type of hemoglobin. Fetal hemoglobin has a higher affinity for O_2 than does adult hemoglobin, allowing fetal blood to pick up O_2 from the maternal blood in the placenta. **Review Figure 49.13, ACTIVITY 49.2**
- CO_2 is transported in the blood principally as bicarbonate ions (HCO_3^-). **Review Figure 49.14**

49.5 How Is Breathing Regulated?

- The basic breathing rhythm is an involuntary function generated by neurons in the medulla and modulated by higher brain centers. The most important feedback stimulus for breathing is the level of CO_2 in the blood. **Review Figures 49.16, 49.17**
- The breathing rhythm is sensitive to feedback from chemoreceptors on the ventral surface of the medulla and in the **carotid** and **aortic bodies** on the large vessels leaving the heart. **Review Figure 49.18**

CHAPTERREVIEW

REMEMBERING

- Which statement about the gas exchange system of birds is *not* true?
 - Respiratory gases are not exchanged in the air sacs.
 - A bird can achieve more complete exchange of O_2 from air to blood than humans can.
 - Air passes through birds' lungs in only one direction.
 - The gas exchange surfaces in bird lungs are the parabronchi.
 - A breath of air remains in the system for two breathing cycles.
- In the human gas exchange system,
 - the lungs and airways are completely collapsed after a forceful exhalation.
 - exhalation is driven by contraction of the diaphragm.
 - the P_{O_2} of the blood leaving the lungs is greater than that of the exhaled air.
 - the amount of air that is moved per breath during normal, at-rest breathing is termed the total lung capacity.
 - P_{CO_2} in the air reaching the alveoli during inhalation is close to zero, as it is in the outside air.
- The hemoglobin of a human fetus
 - is the same as that of an adult.
 - has a higher affinity for O_2 than adult hemoglobin has.
 - has only two protein subunits instead of four.
 - is supplied by the mother's red blood cells.
 - has a higher affinity for BPG than adult hemoglobin has.
- Most CO_2 in the blood is carried
 - in the cytoplasm of red blood cells.
 - as CO_2 dissolved in the plasma.
 - in the plasma as bicarbonate ions.
 - bound to plasma proteins.
 - in red blood cells bound to hemoglobin.

5. Myoglobin

- binds O_2 at P_{O_2} values at which hemoglobin is releasing its bound O_2 .
- has a lower affinity for O_2 than hemoglobin does.
- consists of four polypeptide chains, just as hemoglobin does.
- provides an immediate source of O_2 for muscle cells at the onset of activity.
- can bind four O_2 molecules at once.

UNDERSTANDING & APPLYING

- The blood of a certain species of fish that lives in Antarctica has no hemoglobin. What anatomical and behavioral characteristics would you expect to find in this fish, and why is its distribution limited to the waters of Antarctica?
- In patients with emphysema, the fine structures of alveoli break down, resulting in the formation of larger air cavities in the lungs. Also, the lung tissue becomes less elastic. Give at least two explanations for why such patients have a low tolerance for exercise.
- At what point in the breathing cycle would the pleural cavity pressure be going down while the alveolar pressure is going up? At what point in the breathing cycle would the alveolar pressure be most positive in relation to atmospheric pressure?

ANALYZING & EVALUATING

- Blood banks store whole blood for a much shorter period than they store blood plasma. This is because when blood that has been stored for too long is infused into a patient, it can actually decrease the O_2 available to the patient's tissues. Refer to Figure 9.5 on glycolysis and explain why the affinity of hemoglobin for O_2 increases with time in storage. Hint: Remember that whole blood is living tissue and requires energy, and that a bag of blood is a closed system. Then think about what fuel can supply energy in a closed system.

10. When you suddenly travel to high altitude, you notice an unusual breathing pattern when you are resting. For a while you stop breathing completely; then suddenly you start breathing rapidly for a short time; then you stop breathing again. This can go on and on in a cyclical pattern called Cheyne–Stokes breathing. Think in terms of the changes in partial pressure gradients when you go to high altitudes and explain how the breathing control system could produce this breathing pattern.

11. South American camelids—llamas, alpacas, guanacos, and vicuñas—are native to the Andes Mountains. In the natural habitat of these mammals, more than 5,000 m above sea level, the P_{O_2} is below 85 mm Hg, and the P_{O_2} in the camelids' lungs is about 50 mm Hg. The hemoglobins of these camelids are different from that of humans; the figure shows the O_2 -binding/dissociation curves for human and llama hemoglobins.
- Compared with human hemoglobin, does llama hemoglobin have a higher or a lower affinity for O_2 ?
 - Why would llama hemoglobin be advantageous at high altitudes?
 - How would the characteristics of llama hemoglobin affect the transfer of O_2 from the blood to the tissues of the llama?

- 50.4** What Are the Properties of Blood and Blood Vessels?
- 50.5** How Is the Circulatory System Controlled and Regulated?

An Athlete's Heart Basketball star Reggie Lewis died of heart failure at the age of 27. Although the exact medical situation underlying Lewis's heart problems remains clouded in controversy, great strides have been made in diagnosing a genetic heart condition that can be particularly dangerous for athletes.

ON APRIL 29, 1993, the Boston Celtics met the Charlotte Hornets in an NBA playoff game. The Celtics' star, 27-year-old Reggie Lewis, had just scored 10 points in 3 minutes when he slumped forward and fell to the floor. The team doctor examined him and allowed him to return to the game. But Lewis's legs were "wobbly," and he played only briefly.

Lewis had been experiencing dizzy spells for about a month before the playoff incident. After the playoffs he underwent rigorous testing by cardiologists, who diagnosed him as having a dangerous arrhythmia (irregular heartbeat) indicative of diseased cardiac muscle. Accepting this diagnosis would mean the end of his professional athletic career, and Lewis sought a second opinion. The second medical team concluded that Lewis had undergone a transient irregular heartbeat attributable to normal athletic stresses. The condition was thought to be due to an enlarged heart—a condition common in high-performing athletes. In July 1993, after an hour spent shooting baskets in a pick-up game, Reggie Lewis collapsed and died of heart failure.

Your heart is a muscular pump that, at rest, beats an average of 60 to 70 times per minute. With each beat, it circulates about 70 milliliters of blood through the body. Without taking work or exercise into account, that is 300 liters per hour, 7,200 liters per day, 2.6 million liters per year—no time-outs.

Heart failure is the leading cause of death in the United States, accounting for some one-fourth (about 600,000) of the deaths each year. Heart failure most commonly results from blockage of the vessels that supply the heart muscle with blood, and its risk increases with age. But heart failure is also the leading cause of death among young athletes.

In athletes, the most common cause of heart failure is not blocked vessels but a gene mutation that affects the contractile proteins of the heart. This mutation can lead to a thickening of the walls of the heart. About 0.5 percent of the population has this mutation; most are unaware of it, and most live their entire lives without symptoms.

Diagnosis is improving. In 2008, 33-year-old Cuttino Mobley announced his retirement from basketball after his physical exam revealed arrhythmia and an MRI showed the symptomatic thickening of the heart walls. "Getting the MRI saved my life," Mobley said.

How can the same mutation-based heart condition be fatal to an athlete but innocuous in most other people?

See answer on p. 1046.

50.1 Why Do Animals Need a Circulatory System?

A **circulatory system** consists of a muscular pump (the heart), a fluid (blood), and a series of conduits (blood vessels) through which the fluid can be pumped around the body. Heart, blood, and vessels are also known collectively as a **cardiovascular system** (Greek *kardia*, “heart”; Latin *vasculum*, “vessel”). The function of a circulatory system is to transport things around the body. Preceding chapters discussed how circulatory systems transport heat, hormones, respiratory gases, blood cells, platelets, and cells and molecules of the immune system. Succeeding chapters will add nutrients and waste products to that list. In this section we will describe the general types of circulatory systems found in animals.

Some animals do not have a circulatory system

Single-celled organisms serve all of their needs through direct exchanges with the environment. Such organisms are found mostly in aquatic or very moist terrestrial environments. Similarly, many multicellular aquatic organisms are small or thin enough that all of their cells are close to the external environment. Such species may not have a circulatory system because nutrients, respiratory gases, and wastes can diffuse directly between the cells of their bodies and the environment.

The cells of some larger aquatic multicellular animals without a circulatory system are served by highly branched central cavities called gastrovascular systems that bring the external environment into the animal. All of the cells of a sponge are in contact with, or very close to, the water that surrounds the animal and circulates through its central cavity (see Figure 49.1B). Very small animals without a circulatory system can maintain high levels of metabolism and activity, but larger animals without a circulatory system such as sponges, jellyfishes, and flatworms tend to be inactive, slow, or even sedentary. Large, active animals, however, require a circulatory system.

Circulatory systems can be open or closed

The cells of large, mobile animals are supported by the extracellular fluid. All nutrients—oxygen, fuel, essential molecules—come from that fluid, and the waste products of cell metabolism go into it. Circulatory systems have muscular chambers, or **hearts**, that move the extracellular fluid around the body. In open circulatory systems, extracellular fluid is the same as the fluid in the circulatory system and is called hemolymph. This fluid leaves the vessels of the circulatory system, percolates between cells and through tissues, and then flows back into the heart or vessels of the circulatory system to be pumped out again. In contrast, closed circulatory systems completely contain the circulating fluid (blood) in a continuous system of vessels. Blood cells and large molecules stay within the system, but water and low-molecular-weight solutes leak out of the smallest vessels, the capillaries, which are highly permeable.

In animals with a closed circulatory system, **extracellular fluid** refers to both the fluid in the circulatory system and the

fluid outside it. The fluid in the circulatory system is the blood plasma; the fluid around the cells is the **interstitial fluid** (see Figure 40.1). A 70-kilogram person has a total extracellular fluid volume of about 14 liters. Less than a quarter of it—about 3 liters—is the blood plasma.

Open circulatory systems move extracellular fluid

Open circulatory systems are found in arthropods, mollusks, and some other invertebrate groups. In these systems a muscular pump, or heart, helps move the hemolymph through vessels leading to different regions of the body. The fluid leaves the vessels to filter through the tissues before returning to the heart. In the generalized arthropod shown in **Figure 50.1A**, the fluid returns directly to the heart through openings called ostia. Ostia have valves that allow hemolymph to enter the relaxed heart but prevent it from flowing in the reverse direction when the heart contracts. In mollusks, open vessels collect hemolymph from different regions of the body and return it to the heart (**Figure 50.1B**).

Lest you think that open circulatory systems are inefficient and can support only sluggish lifestyles such as those of mollusks, remember that crabs scuttling along the beach, yellow jackets buzzing around your picnic, and scorpions dashing across the desert all have open circulatory systems.

Closed circulatory systems circulate blood through a system of blood vessels

In **closed circulatory systems**, a system of vessels keeps circulating blood separate from the interstitial fluid. Blood is pumped through this vascular system by one or more muscular hearts, and some components of the blood never leave the vessels. Closed circulatory systems characterize vertebrates and some invertebrate groups, among them annelids.

A simple example of a closed circulatory system is that of the earthworm (**Figure 50.1C**). One large ventral blood vessel carries blood from the worm’s anterior end to its posterior end. Smaller vessels branch off and transport the blood to even smaller vessels serving the tissues in each body segment. In the smallest vessels, respiratory gases, nutrients, and metabolic wastes diffuse between the blood and interstitial fluid. The blood then flows from these vessels into larger vessels that lead into one large dorsal vessel, which carries the blood from the posterior to the anterior end of the body. Five pairs of muscular vessels connect the large dorsal and ventral vessels in the anterior end, thus completing the circuit. The dorsal vessel and the five connecting vessels serve as hearts for the earthworm; their contractions keep the blood circulating. The direction of circulation is determined by one-way valves in the dorsal and connecting vessels.

Closed circulatory systems have several advantages compared with open systems:

- Fluid can flow more rapidly through vessels than through intercellular spaces and can therefore transport nutrients and wastes to and from tissues more rapidly.

(A) Arthropod

(B) Mollusk

(C) Annelid worm

50.1 Circulatory Systems Arthropods, illustrated here by an insect (A), and mollusks such as clams (B) have an open circulatory system. Hemolymph is pumped by a tubular heart and directed to different regions of the body through vessels that open into intercellular spaces. (C) Annelids such as earthworms have a closed circulatory system, in which the cellular and macromolecular elements of the blood are confined in a system of vessels and the blood is pumped through those vessels by one or more muscular hearts.

- By changing the diameter (and hence the resistance) of specific vessels, closed systems can control the flow of blood to selective tissues and organs to match their needs.
- Specialized cells and large molecules that aid in transporting hormones and nutrients can be kept in the vessels but can drop their cargo in the tissues where it is needed.

With all of these “advantages” of closed circulatory systems, you might wonder how some species with open circulatory systems can sustain such high levels of activity. In the case of insects, the answer is clear: insects do not depend on their circulatory systems for respiratory gas exchange (see Chapter 49). The open systems of some other species, such as the crab referred to above, involve elaborate systems of vessels that can direct the movement of tissue fluids from one part of the animal’s body to another.

RECAP 50.1

Circulatory systems consist of a pump and an open or closed set of vessels through which a fluid transports oxygen, nutrients, wastes, and a variety of other substances.

- Circulatory systems are transport systems. What do they transport? [See p. 1026](#)
- Why are many species with open circulatory systems rather limited with respect to metabolic activity, and why does this limitation not apply to insects? [See p. 1026 and Figure 50.1](#)
- What are some advantages of a closed circulatory system? [See pp. 1026–1027](#)

This overview of the open and closed systems found among invertebrates introduced some basic concepts about circulatory systems. Next we will turn to describing the closed circulatory systems of vertebrates.

50.2

How Have Vertebrate Circulatory Systems Evolved?

Vertebrates have a closed circulatory system and a heart with two or more chambers. When a heart chamber contracts, it squeezes the blood, putting it under pressure. Blood then flows out of the heart and into vessels, where pressure is lower. Resistance to flow in the vessels dissipates the pressure imparted to the blood by the heart. One-way valves prevent the backflow of blood as the heart cycles between contraction and relaxation.

As we explore the features of the circulatory systems of different classes of vertebrates, a general evolutionary theme will emerge: as circulatory systems become more complex, the blood that flows to the gas exchange organs (gills or lungs; see Chapter 49) becomes increasingly separated from the blood that flows to the rest of the body.

In fishes, the phylogenetically oldest vertebrates, blood is pumped from the heart to the gills and then to the tissues of the body and back to the heart—a single circuit. In birds and mammals, blood is pumped from the heart to the lungs and back to the heart in a **pulmonary circuit**, and then from the heart to the rest of the body and back to the heart in a **systemic circuit**. In all other vertebrates we see various adaptations for separating the blood flow into pulmonary and systemic circuits.

Both pulmonary and systemic circuits begin with vessels called **arteries** that carry blood away from the heart. Arteries

branch into smaller vessels called **arterioles** that feed blood into capillary beds. **Capillaries** are the tiny, thin-walled vessels where materials are exchanged between the blood and the tissue fluid. Small vessels called **venules** drain capillary beds. The venules join to form larger vessels called **veins** that ultimately deliver blood back to the heart.

We can trace the evolutionary history of vertebrate circulatory systems by comparing the circulatory systems of ray-finned fish, lungfish, amphibians, non-avian reptiles, birds, and mammals.

Circulation in fish is a single circuit

The fish heart has four chambers. Blood returning from all parts of the body collects in a **sinus venosus**, which feeds into the muscular **atrium**. When the atrium contracts, it pumps blood into the more muscular chamber, the **ventricle**. Contraction of the ventricle pushes blood into the last part of the fish heart, the **bulbus arteriosus**, which is a highly elastic chamber. The pressure imparted to the blood by the ventricle stretches the bulbus arteriosus, and its elastic recoil dampens the blood pressure oscillations generated by the beating of the heart. The arterial blood leaving the bulbus arteriosus under pressure flows through the gills, where respiratory gases are exchanged. Blood leaving the gills collects in a large dorsal artery, the **aorta**, which distributes blood to smaller arteries and arterioles leading to all the organs and tissues of the body. In the tissues, blood flows through beds of tiny capillaries, collects in venules and veins, and eventually returns to the sinus venosus of the heart. The unidirectional flow of blood in this circuit is enabled by one-way valves between the sinus venosus and the atrium, between the atrium and the ventricle, and between the ventricle and the bulbus arteriosus.

Most of the pressure imparted to the blood by the contraction of the ventricle is dissipated as a result of resistance to flow in the many narrow spaces in the gill lamellae. Therefore blood leaving the gills and entering the aorta is under low pressure, limiting the capacity of the fish circulatory system to supply the tissues with oxygen and nutrients. Yet this limitation on arterial blood pressure does not seem to limit swimming performance. Some species, such as tuna and marlin, can swim at remarkably high rates of speed for long distances.

The evolutionary transition from breathing water to breathing air had important consequences for the vertebrate circulatory system. An example of how the system changed to serve a primitive lung can be seen in the African lungfish.

Lungfish evolved a gas-breathing organ

Lungfish are periodically exposed to water with low oxygen content or to situations in which their aquatic environment dries up. The adaptation that deals with these conditions is an outpocketing of the gut that serves as a lung. The lung contains many thin-walled blood vessels, so blood flowing through those vessels can pick up oxygen from air gulped into the lung.

How does the lungfish circulatory system take advantage of this new organ? In fishes, the gills are arranged on supportive gill arches (see Figure 49.5). Blood flows into the gill arch in an afferent arteriole and leaves in an efferent arteriole. In lungfishes, the blood vessels in the posterior pair of gill arteries have been modified to be a low-resistance conduit for blood to the lung, and a new vessel carries oxygenated blood from the lung back to the heart. In addition, two anterior gill arches have lost their gills, and their blood vessels deliver blood from the heart directly to the dorsal aorta. Because a few of the gill arches retain gills, the African lungfish can breathe either air or water.

The lungfish heart partially separates its flow of blood into pulmonary and systemic circuits; it has a partially divided atrium. The left side receives oxygenated blood from the lung and the right side receives deoxygenated blood from the sinus venosus. These two bloodstreams stay mostly separate as they flow through the ventricle and the bulbus arteriosus. As a result, oxygenated blood goes mostly to the anterior gill arteries leading to the dorsal aorta, and deoxygenated blood goes mostly to the other gill arches that have functional gills as well as to the gill arteries that serve the lung.

We can conclude that the lungfish lung evolved as a means of supplementing oxygen uptake from the gills. When the water is oxygenated, the lungfish can obtain oxygen through its gills; but in oxygen-depleted water, it can depend on getting oxygen from its lung. Associated modifications of the lungfish

vascular system set the stage for the evolution of separate pulmonary and systemic circulations in higher vertebrates.

Amphibians have partial separation of systemic and pulmonary circulation

In adult amphibians, a single ventricle pumps blood to the lungs and the rest of the body, but two atria receive blood returning to the heart. The left atrium receives oxygenated blood from the lungs, and the right atrium receives deoxygenated blood from the body.

Because both atria deliver blood to the same ventricle, the oxygenated and deoxygenated blood could mix, in which case blood going to the tissues would not carry a full load of oxygen. Mixing is limited, however, because anatomical features of the ventricle direct the flow of deoxygenated blood from the right atrium to the pulmonary circuit and the flow of oxygenated blood from the left atrium to the aorta. Partial separation of pulmonary and systemic circulation has the advantage of allowing blood destined for the tissues to sidestep the large pressure drop that occurs in the gas exchange organ. Blood leaving the amphibian heart for the tissues moves directly to the aorta, and hence to the body, at a higher pressure than if it had first flowed through the lungs.

Amphibians have another adaptation for oxygenating their blood: they can pick up a considerable amount of oxygen in blood flowing through small blood vessels in their skin.

Reptiles have exquisite control of pulmonary and systemic circulation

As described in Chapter 33, the reptiles include turtles, snakes, lizards, crocodilians, and birds (see Figure 33.20). Crocodilians and birds have cardiovascular systems with two completely separated ventricles, creating a four-chambered heart. All other reptiles have ventricles that are not completely separated into left and right chambers.

Consider the behavior, ecology, and physiology of ectothermic reptiles (i.e., excluding birds). Many are active, powerful, fast animals, but their activity comes in bursts that are interspersed with long periods of inactivity. At these times the

animals' metabolic rates are much lower than the resting metabolic rates of the endothermic birds and mammals. So enormous is the range of metabolic demand in ectothermic reptiles that they do not need to breathe continuously. Some species are accomplished divers and spend long periods under water, where they cannot breathe air.

When these animals are not breathing, it would be a waste of energy for them to pump blood through their lungs. Thus they have evolved the capability to send blood to the lungs and the rest of the body when they are breathing, but when they are not breathing, they can bypass the pulmonary circuit and pump all the blood to the body. How do they do this?

In ectothermic reptiles with a three-chambered heart—that is, the turtles, snakes, and lizards—the ventricle is partially divided into left and right halves by a septum. Oxygenated blood from the lungs enters the left side of the ventricle through the left atrium. Deoxygenated blood from the body enters the right side of the ventricle through the right atrium. These species have two aortas, left and right. The left aorta is positioned so that it receives oxygenated blood from the left side of the ventricle. The right aorta, however, is positioned so that it can receive blood from either the right or left side of the ventricle.

When the animal is breathing air, the resistance in the pulmonary circuit is lower than the resistance in the systemic circuit, so blood from the right side of the ventricle tends to flow into the pulmonary artery rather than the right aorta. When the animal is not breathing, pulmonary vessels constrict, resistance in the pulmonary circuit goes up, and blood from the right side of the ventricle tends to flow into the right aorta. As a result, blood from both sides of the ventricle flows through both aortas to the systemic circuit.

Crocodilians, like birds, have two completely separated ventricles. Unlike birds, they have two aortas, one originating in each ventricle. But there is a connection between the two aortas just as they leave the heart, and this connection enables them to alter the proportions of blood going to their pulmonary and systemic circuits. When a crocodile or alligator

is breathing and resistance in the pulmonary circuit is low, backpressure from the stronger left ventricle closes the valve between the right ventricle and the right aorta, forcing all of the blood from the right ventricle to flow into the pulmonary circuit. When the animal stops breathing, pulmonary vessels constrict, resistance in the pulmonary circuit rises, and blood from the right ventricle flows into the right aorta. This ability of all ectothermic reptiles to direct blood to their pulmonary or systemic circuits is highly adaptive for their lifestyle of intermittent breathing.

Birds and mammals have fully separated pulmonary and systemic circuits

The four-chambered hearts of birds and mammals have completely separate pulmonary and systemic circuits. Separate circuits have several advantages for these active animals with continuously high metabolic rates:

- Oxygenated and deoxygenated blood cannot mix; therefore the systemic circuit always receives blood with the highest oxygen content.
- Respiratory gas exchange is maximized because the blood with the lowest oxygen content and highest CO₂ content is sent to the lungs.
- Separate systemic and pulmonary circuits can operate at different pressures.

The tissues of birds and mammals have high nutrient demands and thus a very high density of blood vessels, requiring the heart to generate a high blood pressure to perfuse all the vessels of the systemic circuit. The pulmonary circuit of these animals receives a blood flow equal to that of the systemic circuit, but the lungs have far fewer blood vessels. Thus the pulmonary circuit of birds and mammals can function at lower pressures, and the four-chambered heart makes that possible.

Go to Activity 50.1 Vertebrate Circulatory Systems
Life10e.com/ac50.1

RECAP 50.2

The closed circulatory system of vertebrates has evolved from a single circuit system in fishes to separate pulmonary and systemic circuits in birds and mammals.

- Explain why fish cannot supply blood to their tissues at high pressure. [See p. 1028](#)
- By comparing lungfish and amphibian circulatory systems, explain how a heart with two separate atria could have evolved. [See pp. 1028–1029](#)
- What are some advantages of separate pulmonary and systemic circuits? [See pp. 1029–1030](#)

50.3

How Does the Mammalian Heart Function?

Mammals have hearts consisting of a right and a left atrium and a right and a left ventricle. We can use the human heart as our example (**Figure 50.2**). The right ventricle pumps blood through the pulmonary circuit, and the left ventricle pumps blood through the systemic circuit.

One-way valves between the atria and ventricles, the **atrio-ventricular (AV) valves**, prevent backflow of blood into the atria when the ventricles contract. The **pulmonary valve** and **aortic valve**, one-way valves between the ventricles and the major arteries, prevent backflow of blood into the ventricles when they relax.

In this section we will describe the flow of blood through the heart and body and examine the unique electrical properties of cardiac muscle that result in the rhythmic contractions of the heart.

Blood flows from right heart to lungs to left heart to body

The heart's right atrium receives deoxygenated blood from the **superior** (upper) **vena cava** and the **inferior** (lower) **vena cava** (see Figure 50.2)—the large veins that collect blood returning to the heart from the upper and lower body, respectively. The veins of the heart itself also drain into the right atrium. From the right atrium, the blood flows through the right AV valve into the right ventricle. Most of the filling of the ventricle results from passive flow while the heart is relaxed between beats. Just at the end of this period of passive ventricular filling, the atrium contracts and adds a little more blood to the

ventricular volume. The right ventricle then contracts, causing the AV valve to close and pumping the blood into the **pulmonary artery** leading to the lungs.

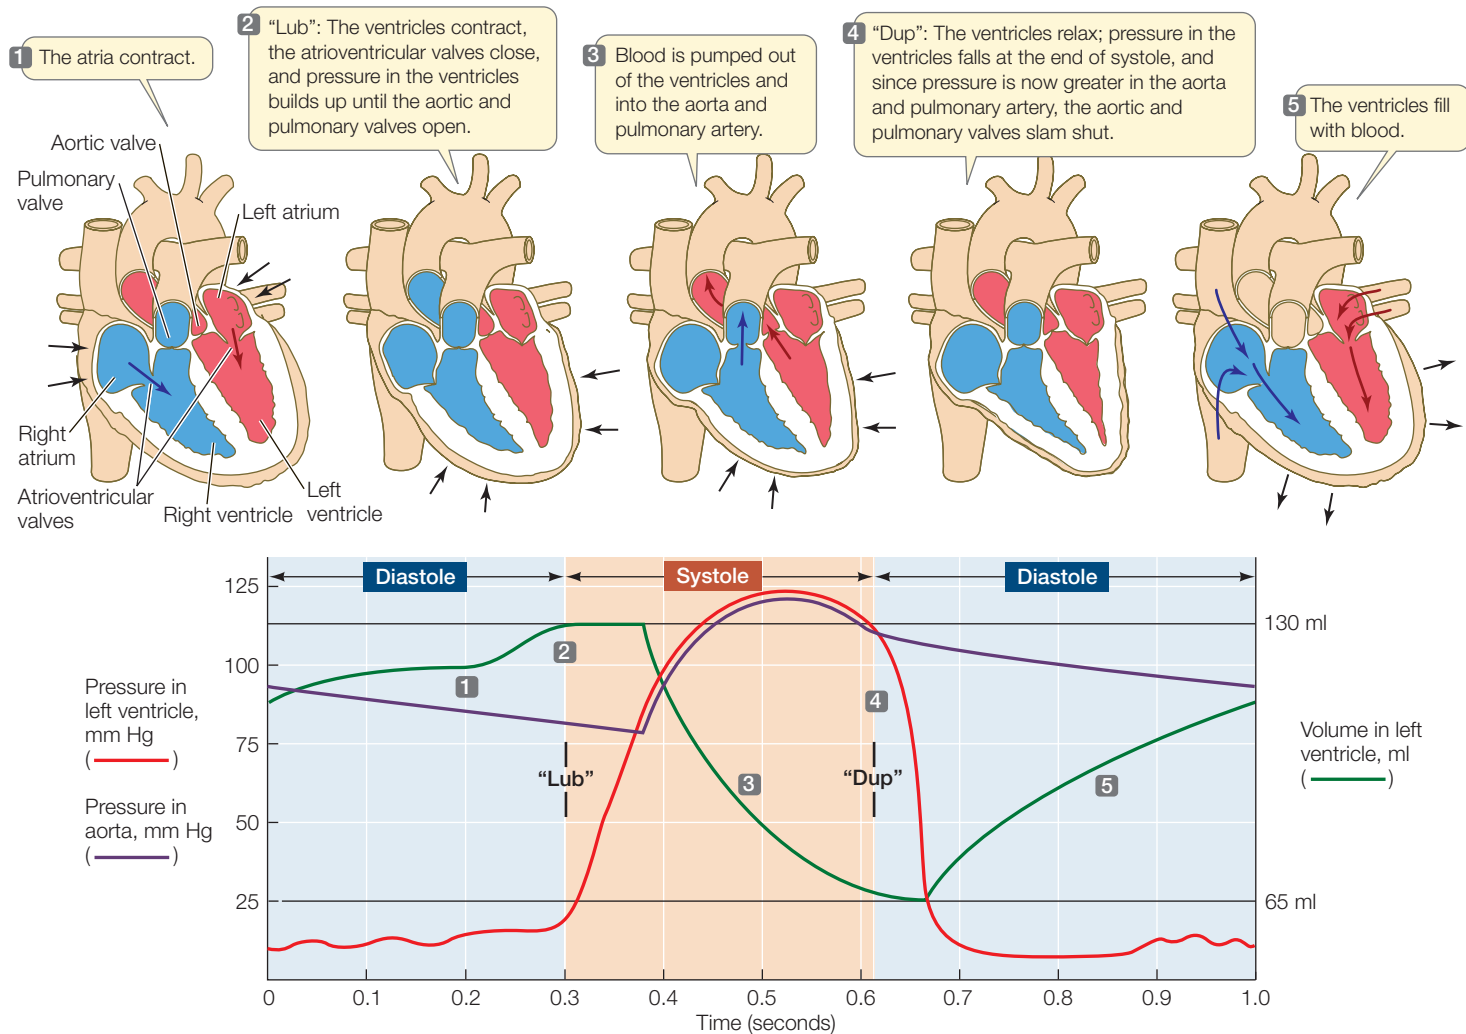

Pulmonary veins return the oxygenated blood from the lungs to the left atrium, from which the blood enters the left ventricle through the left AV valve. As on the right side of the heart, most left ventricular filling is passive, but ventricular filling reaches a maximum when the atria contract.

The walls of the left ventricle are powerful muscles that contract around the blood with a wringing motion starting from the bottom. When pressure in the left ventricle is high enough to push open the aortic valve, blood rushes into the aorta to begin its circulation throughout the body. In Figure 50.2, observe that the walls of the left ventricle are thicker than those of the right ventricle. The left ventricle has to propel blood through many more kilometers of blood vessels than does the right

ventricle, and must therefore push against more resistance, even though both ventricles pump the same volume of blood.

Both sides of the heart contract at the same time. Contraction of the two atria, followed by contraction of the two ventricles and then relaxation, is the **cardiac cycle**. The cardiac cycle is divided into two phases: **systole** (pronounced *sís-toll-ee*), when the ventricles contract, and **diastole** (*die-ás-toll-ee*), when the ventricles relax (Figure 50.3). At the very end of diastole (step 1 in Figure 50.3), just before the ventricles contract, the atria contract and top off the volume of blood in the ventricles.

The sounds of the cardiac cycle—the “lub-dup” heard through a stethoscope—are created by the heart valves slamming shut. The closing and opening of these valves are simple mechanical events resulting from pressure differences on the two sides of the valves. As the ventricles begin to contract (step 2 in Figure 50.3), the pressure in them rises above the pressure in the atria, so the

50.3 The Cardiac Cycle The rhythmic contraction (systole) and relaxation (diastole) of the ventricles is called the cardiac cycle. The representation below shows pressure and volume changes during the cardiac cycle for the left ventricle only.

 **Go to Animated Tutorial 50.1**
The Cardiac Cycle
Life10e.com/at50.1

AV valves close ("lub"). When the ventricles begin to relax (step 4 in Figure 50.3), the high pressure in the aorta and pulmonary artery closes the aortic and pulmonary valves ("dup").

Defective valves that do not close completely produce turbulent blood flow and the sounds known as heart murmurs. For example, if an AV valve does not close completely, blood will flow back into the atrium with a "whoosh" at the beginning of systole.

Blood pressure changes associated with the cardiac cycle can be measured in the large artery in your arm by using an inflatable pressure cuff and a pressure gauge, together called a sphygmomanometer, and a stethoscope (Figure 50.4). This method measures the minimum pressure necessary to compress an artery so blood does not flow through it at all (the systolic value) and the minimum pressure that causes intermittent flow through the artery (the diastolic value). A conventional

blood pressure reading is expressed as the systolic value placed over the diastolic value. Healthy values for a young adult might be 120 millimeters of mercury (mm Hg) during systole and 70 mm Hg during diastole, or 120/70.

The heartbeat originates in the cardiac muscle

Cardiac muscle has unique adaptations that enable it to function as a pump. First, cardiac muscle cells are in electrical contact with one another through gap junctions, which enable action potentials (see Section 45.2) to spread rapidly from cell to cell. Because a spreading action potential stimulates contraction, large groups of cardiac muscle cells contract in unison. This coordinated contraction is essential for pumping blood effectively.

Second, some cardiac muscle cells are **pacemaker cells** that can initiate action potentials without stimulation from the nervous system. When they fire action potentials, they stimulate neighboring cells to contract. The primary pacemaker of the heart is a group of modified cardiac muscle cells, the **sinoatrial node**, located at the junction of the superior vena cava and right atrium (see Figure 50.7). The resting membrane potentials of these cells are less negative than those of other cardiac muscle cells and are not stable; instead they gradually become even less negative until they reach threshold for initiating an

action potential. The action potentials of pacemaker cells are very different from those of neurons and other muscle cells (see Figure 45.10). They are slower to rise; they are broader; and they are slower to return to resting potential (**Figure 50.5A**). These properties of pacemaker cells are due to the ion channels in their membranes.

Pacemaker potentials involve Na^+ , Ca^{2+} , and K^+ channels (**Figure 50.5B**). As we discussed in Section 45.2, when Na^+ or Ca^{2+} channels open, positive charges flow into the cell and the membrane potential becomes less negative. When K^+ channels open, positive charges flow out of the cell and the membrane potential becomes more negative. Because the Na^+ channels of pacemaker cells are open more of the time than are those of other cardiac muscle cells, the pacemaker resting potential is less negative. The action potential of pacemaker cells is due to voltage-gated Ca^{2+} channels rather than voltage-gated Na^+ channels as in neurons, skeletal muscle, and other cardiac muscle cells. These Ca^{2+} channels open and close more slowly than voltage-gated Na^+ channels, explaining the shape of pacemaker action potentials.

50.5 The Pacemaker Potential (A) The resting potential of the pacemaker cells of the sinoatrial node is less negative and gradually drifts upward between action potentials. Action potentials are slow to rise and are broad. These characteristics are due to properties of Na^+ , K^+ , and two types of Ca^{2+} channels. (B) At rest, sinoatrial pacemaker cells are more permeable to Na^+ than are neurons or other muscle cells. During rest, the cation channels gradually close, but some voltage-gated Ca^{2+} channels open; these are designated T-type channels because their opening is transient. When a threshold is reached, other voltage-gated Ca^{2+} channels open (designated as L-type for long-lasting), generating the action potential.

50.4 Measuring Blood Pressure Blood pressure in the major artery of the arm can be measured with a device called a sphygmomanometer, which combines an inflatable cuff and a pressure gauge. A stethoscope is also used to detect sounds created by the blood vessels in response to changes in pressure during the cardiac cycle.

The unstable resting potential of pacemaker cells is due to the behavior of cation channels. As in neurons and skeletal muscle cells, there are voltage-gated K^+ channels that slowly open on the rising phase of the action potential. The opening of these channels allows K^+ ions to leave the cell and thereby restore the negative charge on the cell membrane. That restoration of a negative membrane potential causes the opening of a unique class of voltage-gated cation channels that mostly conduct Na^+ . At the same time, the voltage-gated K^+ channels that opened during the action potential slowly close. The

result is that there are more Na^+ ions coming into the cell than there are K^+ ions leaving, and the cell membrane potential gradually becomes less negative (see Figure 50.5).

The gradual rise in membrane potential closes the channels that allow Na^+ to move into the cell, but as the membrane

50.6 The Autonomic Nervous System Controls Heart Rate

Heart Rate Isolated pacemaker cells continue firing action potentials in a culture dish. Neurotransmitter signals from the two divisions of the autonomic nervous system speed up and slow down the rate at which the pacemaker membrane potential drifts upward, thereby controlling the rate at which pacemaker cells fire action potentials.

becomes less negative, some Ca^{2+} channels open, causing the membrane potential to continue its gradual rise. Eventually this rising membrane potential reaches threshold for the major voltage-gated Ca^{2+} channels, and another action potential is generated. The intricate interaction of these ion channels through their effects on membrane potential causes the rhythmic generation of action potentials that characterizes pacemaker cells.

The autonomic nervous system controls the heartbeat (speeds it up or slows it down) by influencing the rate at which the resting potentials of pacemaker cells drift upward (**Figure 50.6**). Norepinephrine (NE) released onto pacemaker cells by sympathetic nerves increases the permeability of the Na^{+} channels and the Ca^{2+} channels. The result is that the resting potential of the pacemaker cells drifts up more rapidly, the interval between action potentials is decreased, and the heart beats faster. Conversely, the parasympathetic neurotransmitter acetylcholine (ACh) has opposite effects. ACh increases the permeability of K^{+} channels so that the membrane potential becomes even more negative following an action potential and rises more slowly. ACh also decreases the permeability of the Ca^{2+} channels so that the rate of rise of the membrane potential slows, the interval between pacemaker action potentials lengthens, and the heart slows down.

A conduction system coordinates the contraction of heart muscle

A normal heartbeat begins with an action potential in the sinoatrial node (**Figure 50.7**). This action potential spreads rapidly throughout the electrically coupled cells of the atria, causing them to contract in unison. Because there are no gap junctions between the cells of the atria and those of the ventricles, the action potential does not spread directly to the ventricles. Therefore the ventricles do not contract in unison with the atria.

How does the action potential move from the atria to the ventricles? Situated at the junction of the atria and the ventricles is a nodule of modified cardiac muscle cells—the **atrioventricular node**—which is stimulated by the depolarization of the atria. With a slight delay, it generates action potentials that are conducted to the ventricles via the **bundle of His**, which consists of modified cardiac muscle fibers that do not contract but do conduct action potentials. These fibers divide into right and left

bundle branches that run to the tips of the ventricles and then spread throughout the ventricular muscle mass as **Purkinje fibers**. These conducting fibers ensure that the cardiac action potential spreads rapidly and evenly throughout the ventricular muscle mass, starting at the very bottom of the ventricles. The short delay in the spread of the action potential imposed by the atrioventricular node ensures that the atria contract before the ventricles do, so that the blood passes progressively from the atria to the ventricles to the arteries.

Electrical properties of ventricular muscles sustain heart contraction

Electrical properties of ventricular muscle fibers allow them to contract for about 300 milliseconds—much longer than those of skeletal muscle fibers. As in neuronal and skeletal muscle action potentials, the rising phase of the ventricular muscle cell action potentials is due to the opening of voltage-gated Na^{+} channels. Unlike neurons and skeletal muscle fibers, however, ventricular muscle cells remain depolarized for a long time. This extended plateau of the action potential is due to sustained opening of voltage-gated Ca^{2+} channels (**Figure 50.8**). Like other muscle, cardiac muscle is stimulated to contract when Ca^{2+} is available to bind with troponin (see Figure 48.6). As long as Ca^{2+} remains in the sarcoplasm, the ventricular muscle cells continue to contract.

To terminate systole and allow the ventricles to fill again, Ca^{2+} must be rapidly cleared from the sarcoplasm of the ventricular cells. Ca^{2+} pumps in the sarcoplasmic reticulum membrane actively transport Ca^{2+} ions out of the sarcoplasm and into the sarcoplasmic reticulum; there, the ions are sequestered until the next action potential triggers another round of Ca^{2+} release and muscle contraction. Thus the rate of cycling of Ca^{2+} into and out of the sarcoplasmic reticulum puts limits on the heart rate and strength of contraction of the ventricle (**Figure 50.9**).

The drug digitalis has been used since the late 1700s to treat weakened hearts or hearts with irregular patterns of contraction. Digitalis strengthens and slows the heartbeat by slowing the reuptake of Ca^{2+} by the sarcoplasmic reticulum and thereby increasing the concentration of Ca^{2+} in the sarcoplasm. Before being introduced into the practice of medicine, digitalis prepared from the purple foxglove plant (*Digitalis purpurea*) was a folk remedy for heart problems.

Heart at rest (diastole)**Atrial contraction****Ventricular contraction (systole)**

50.7 The Heartbeat Pacemaker cells in the sinoatrial node initiate the heartbeat by firing action potentials that spread through the electrically coupled atrial muscle. The atrial action potential eventually spreads to the atrioventricular node which, with a delay, conducts it through the bundle of His and Purkinje fibers to the cells of the ventricles.

The ECG records the electrical activity of the heart

Electrical events in the cardiac muscle during the cardiac cycle can be recorded by electrodes placed on the surface of the body. Such a recording is an **electrocardiogram**, or **ECG**. **EKG** is also used because German physicians who invented the method used the Greek spelling (*kardia*) and called it the elektrokardiogramm. The ECG is an important tool for diagnosing heart problems (**Figure 50.10A**).

50.8 The Action Potential of Ventricular Muscle Fibers (A) The three phases of the action potential of ventricular muscle fibers are due to the opening and closing of voltage-gated channels. (B) At the initiation of the action potential, voltage-gated Na⁺ channels open rapidly but briefly. At the same time, but more slowly, K⁺ channels are closing and Ca²⁺ channels are opening. The open Ca²⁺ channels sustain the depolarization. Repolarization occurs when the Ca²⁺ channels close, and the slow opening of the K⁺ channels also contribute to the repolarization.

The action potentials that sweep through the muscles of the atria and ventricles before they contract are such massive, localized electrical events that they cause electric currents to flow throughout the body. Electrodes placed at different locations on the skin detect those currents at different times and register a voltage difference between them. The appearance of the ECG depends on the placement of the electrodes. Electrodes placed on the right wrist and left ankle produced the normal ECG shown in **Figure 50.10B**. The wave patterns of the ECG are designated P, Q, R, S, and T, each letter representing a particular event in the cardiac muscle, as shown in the figure.

INVESTIGATINGLIFE

50.9 Hot Fish, Cold Heart In “hot” fish like the bluefin tuna, highly active tissues such as the swimming muscles remain warm while the heart temperature falls (see Figure 40.14). How can a “cold heart” meet the metabolic demands of active muscles?

Barbara Block and her colleagues demonstrated that the sarcoplasmic reticulum in the heart muscle cells of a bluefin takes up Ca^{2+} much more rapidly after each contraction than is the case for “cold” fish species, allowing the bluefin heart to beat at a faster rate.^a

HYPOTHESIS The bluefin tuna can maintain a fast heart rate at low temperatures because its heart muscle cells cycle Ca^{2+} more rapidly in typical fishes.

Method Isolate membrane-enclosed vesicles derived from sarcoplasmic reticulum (SR) from hearts of bluefin (a “hot” fish) and from albacore and yellowfin tuna (“cold” fish). Incubate

the SR vesicles in a solution containing Ca^{2+} and measure their rate of Ca^{2+} uptake. Repeat the experiment at a range of temperatures.

Results Over a wide range of temperatures, SR vesicles from bluefin take up Ca^{2+} more rapidly than do those from the other fishes.

CONCLUSION The sarcoplasmic reticulum in bluefin heart muscle cycles Ca^{2+} more rapidly than in other tuna species, allowing the heart to beat faster at cold temperatures.

50.10 The Electrocardiogram (A) An electrocardiogram (abbreviated as ECG or EKG) is used to monitor heart function. Electrodes attached to the person on the treadmill record an ECG that is amplified and displayed on a monitor. (B) Variations from the normal pattern shown here can be used to diagnose heart problems.

WORKING WITH DATA:

Warm Fish with Cold Hearts

Original paper

Landeira-Fernandez, A., M. M. Morrisette, J. M. Blanc, and B. A. Block. 2004. Temperature dependence of the Ca^{2+} -ATPase (SERCA2) in the ventricles of tuna and mackerel. *American Journal of Physiology: Regulatory, Integrative, and Comparative Physiology* 286: R398–R404.

Analyze the Data

“Hot fish” like the bluefin tuna (see Figure 40.14) face a dilemma when swimming in cold waters. As in all fish, the rate at which their hearts can beat goes down as the heart temperature goes down, which lowers the supply of oxygenated blood to the tissues of the body. But, unlike in “cold fish,” the swimming muscles in bluefin tuna remain warm even in cold waters, so their demand for oxygen remains high. How does a bluefin tuna maintain an adequate blood supply to the swimming muscles at cold temperatures? The heart muscle of the bluefin tuna is adapted to cycle Ca^{2+} more rapidly than the heart muscle of “cold fish,” allowing the heart to contract more frequently. Barbara Block and her colleagues hypothesized that this adaptation could be due to an increased ability to sequester Ca^{2+} back into the sarcoplasmic reticulum after each contraction (see Figure 50.9). The researchers isolated vesicles derived from the sarcoplasmic reticulum of heart muscle from three different fish: one “hot fish” (bluefin tuna) and two closely related “cold fish” (albacore and yellowfin tuna). The vesicles were incubated in a Ca^{2+} solution and the rate of Ca^{2+} uptake into the vesicles measured at a range of temperatures. The results are shown in the top panel of the figure at the right.

QUESTION 1

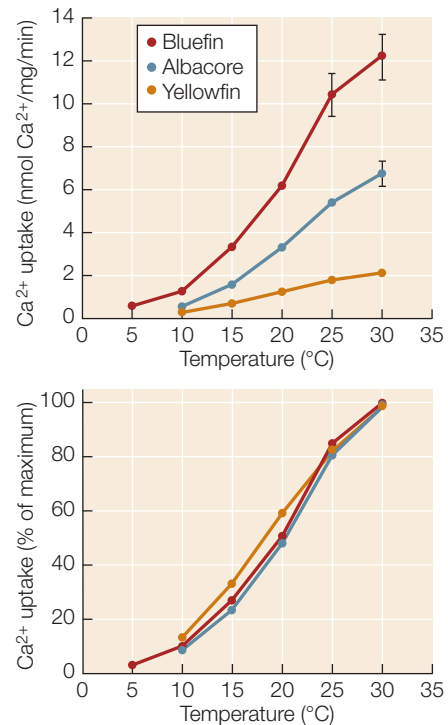

How do these data support the hypothesis that bluefin tuna have an increased ability to sequester Ca^{2+} in the sarcoplasmic reticulum? How would these data look if the hypothesis weren't true?

QUESTION 2

Based on these data, which fish would you expect to be able to achieve the highest cardiac output at 25°C, albacore or yellowfin? Albacore at 25°C or bluefin at 15°C?

QUESTION 3

The high rate of Ca^{2+} uptake observed in the bluefin vesicles means that the Ca^{2+} /ATPase pumps in the sarcoplasmic reticulum of the bluefin must be either different from those of other fish or more numerous. To distinguish between these two possibilities, the researchers plotted their data in a different way; this time they expressed the uptake rates as a percentage of the maximum rate (the rate at 30°C). This plot is shown in the bottom panel of the figure. What does this plot tell you about the properties of the Ca^{2+} /ATPase pumps in the different fish? What is the explanation for the higher rate of Ca^{2+} uptake in bluefin tuna?

RECAP 50.3

The mammalian heart has two atria and two ventricles. Modified cardiac muscle tissue in the right atrium functions to spontaneously generate pacemaker action potentials. Other modified cardiac muscle tissue between the atria and ventricles and throughout the ventricles conducts those signals and coordinates the heart contraction. Broad action potentials in ventricular muscle reflect Ca^{2+} cycling in the ventricular muscle cells and make sustained contractions possible.

- Trace the path of blood through both sides of the heart, naming the major blood vessels and heart valves. **See pp. 1030–1031 and Figure 50.2**
- Differentiate systole and diastole and describe the events of the cardiac cycle. **See p. 1031 and Figure 50.3**
- How do cells of the sinoatrial node generate the heartbeat? **See pp. 1032–1034 and Figures 50.5 and 50.7**
- What determines the duration of the contraction of the ventricles during systole? **See p. 1034 and Figure 50.8 and 50.9**

Next we will consider the composition of the blood and the characteristics of the vessels through which blood circulates around the body, illustrating once again how structure serves function. We will also consider the role of the lymphatic vessels that return interstitial fluid to the blood.

50.4

What Are the Properties of Blood and Blood Vessels?

Blood is a connective tissue. It consists of cells suspended in an extracellular matrix of complex, yet specific, composition. The unusual feature of blood is that the extracellular matrix is a liquid, so blood is a fluid tissue.

The cells of the blood can be separated from the fluid matrix, called **plasma**, by centrifugation (**Figure 50.11**). If a sample of blood is spun in a centrifuge, all the cells move to the bottom of the tube, leaving the clear, straw-colored plasma on top. The packed-cell volume, or hematocrit, is the percentage of the

Blood is withdrawn from the arm, placed in a test tube, and centrifuged.

50.11 The Composition of Blood Blood consists of a complex aqueous solution (the plasma) and numerous cell types and cell fragments. The hematocrit (arrow) is a measure of the cellular portion as a percentage of total blood volume.

blood volume made up by red blood cells. Normal hematocrit is about 42 percent for women and 46 percent for men, but these values can vary considerably. They are usually higher, for example, in people who live and work at high altitudes, because the low oxygen concentrations there stimulate the production of more red blood cells.

Here we will consider two elements in blood: the red blood cells and the platelets, which are pinched-off fragments of cells. White blood cells, or leukocytes, are the cells of the immune system, discussed in Chapter 42.

Red blood cells transport respiratory gases

Most of the cells in the blood are **erythrocytes**, or red blood cells. Mature red blood cells are biconcave, flexible discs packed with hemoglobin. Their function is to transport respiratory gases. Their shape gives them a large surface area for gas exchange, and their flexibility enables them to squeeze through narrow capillaries. Men have 4.5 to 6.0 million red blood cells per microliter of blood, and women have 3.5 to 5.0 million.

Red blood cells, as well as all the other cellular components of blood, are generated by stem cells in the bone marrow, particularly in the ribs, breastbone, pelvis, vertebrae, and the long bones of the limbs. Red blood cell production is controlled by a hormone, **erythropoietin**, which is released by cells in the kidneys in response to insufficient oxygen—**hypoxia**. Many tissues respond to hypoxia by expressing a transcription factor called hypoxia-inducible factor 1 (HIF-1). When the kidneys

become hypoxic and express HIF-1, one of the actions of the transcription factor is to activate the gene encoding erythropoietin. Increased circulating erythropoietin extends the lives of mature red blood cells and stimulates production of new red blood cells in the bone marrow.

Under normal conditions, your bone marrow produces about 2 million red blood cells every second. Developing red blood cells divide many times while still in the bone marrow, and during this time they produce hemoglobin. When hemoglobin makes up about 30 percent of the immature red blood cell, the nucleus, endoplasmic reticulum, Golgi apparatus, and mitochondria begin to break down. This process is almost complete when the newly mature red blood cell squeezes between the endothelial cells of blood vessels in the bone marrow and enters the circulation. Loss of nuclei from the red blood cells occurs in most mammalian species, but the red cells of a few mammals and of all other vertebrates are nucleated.

Each red blood cell circulates for about 120 days. As it gets older, its membrane becomes less flexible and more fragile, so older red blood cells are more likely to rupture as they bend to fit through narrow capillaries. Red blood cells are particularly squeezed in the **spleen**, an organ that sits near the stomach in the upper left side of the abdominal cavity. The spleen has many sinuses (cavities) that serve as reservoirs for red blood cells. To get into the sinuses, however, the red blood cells must squeeze between spleen cells. When old red blood cells are ruptured by this squeezing, their remnants are taken up and degraded by macrophages (a class of white blood cells that ingest debris and foreign materials).

50.12 Blood Clotting (A) Damage to a blood vessel initiates a cascade of events that produce a fibrin meshwork. (B) As the meshwork forms, red blood cells are enmeshed in the fibrin threads, forming a clot, as shown in this color-enhanced electron micrograph.

Platelets are essential for blood clotting

Besides producing erythrocytes and leukocytes, the bone marrow stem cells described in Section 42.1 also produce cells called megakaryocytes. Megakaryocytes are large cells that remain in the bone marrow and release cell fragments called **platelets** into the circulation. A platelet is just a tiny fragment of a cell without cell organelles, but it is packed with enzymes and chemicals necessary for its function: sealing leaks in blood vessels and initiating **blood clotting** (Figure 50.12).

Damage to a blood vessel exposes collagen fibers. An encounter with collagen fibers activates a platelet. The platelet swells, becomes irregularly shaped and sticky, and releases chemicals that activate other platelets and initiate the clotting of blood. The sticky platelets also form a plug at the damaged site.

Blood clotting requires many steps and many clotting factors, most of which are circulating in the blood in an inactive form. The absence of any one of these proteins can impair clotting and cause excessive bleeding. Because the liver produces most of the clotting factors, liver diseases such as hepatitis and cirrhosis can result in excessive bleeding. People with hemophilia experience uncontrolled bleeding because of a genetic inability to produce one of the clotting factors.

Blood clotting factors participate in a cascade of chemical activations of other substances circulating in the blood. The cascade begins with blood vessel and other tissue damage that exposes the blood to proteins such as collagen that are normally separated from the blood by endothelial cells lining the blood vessels. This exposure activates platelets and begins the clotting factor cascade. The end result of this cascade is to convert an inactive circulating enzyme, **prothrombin**, to its active form, **thrombin**. Thrombin cleaves molecules of **fibrinogen**, a plasma protein, forming insoluble threads of **fibrin**. The fibrin threads form the

meshwork that binds platelets, seals the vessel, and provides a scaffold for the formation of scar tissue (see Figure 50.12).

Arteries withstand high pressure, arterioles control blood flow

Blood circulates through the vertebrate body in a system of closed vessels, and the properties of those different classes of vessels reflect their functions. The walls of the large arteries have many extracellular collagen and elastin fibers, which enable them to withstand the high blood pressures generated by the heart (Figure 50.13A). These elastic tissues have another important function: as we saw with the bulbus arteriosus in fish, they are stretched during systole, and thereby store some of the energy imparted to the blood by the heart. Elastic recoil during diastole returns this energy to the blood by squeezing it and pushing it forward. As a result, even though pressure in the arteries pulsates with the beating of the heart, the flow of blood is smoother than it would be through a system of rigid pipes.

Smooth muscle cells in the walls of the arteries and arterioles constrict or dilate those vessels. When the diameter of the vessels changes, their resistance to blood flow also changes, and the amount of blood flowing through them changes as a result. Neural and hormonal mechanisms act on smooth muscle cells in the walls of the arteries and arterioles, controlling the flow of blood through these vessels. The arterioles are referred to as resistance vessels because their resistance can vary to control the blood flow to specific tissues.

Materials are exchanged in capillary beds by filtration, osmosis, and diffusion

Beds of capillaries lie between arterioles and venules (Figure 50.13B). Few cells are more than a few cell diameters away from a capillary. (Notable exceptions include developing

50.13 Anatomy of Blood Vessels (A) The different anatomical characteristics of arteries and veins match their functions. (B) Blood from the arterial system feeds into capillary beds, where exchanges with the interstitial fluid occur. The venous system returns the blood to the heart. (C) The area encompassed by each vessel type is graphed along with the pressure and velocity of the blood within them.

Go to Activity 50.3 Structure of a Blood Vessel
Life10e.com/ac50.3

oocytes and the cells of the lens and cornea.) The cells' needs are served by the exchange of materials between blood and interstitial fluid across the capillary walls. Capillary walls are thin and permeable to water and many solutes. Also, blood flows slowly through capillaries, allowing time for exchange.

It may seem strange that blood flows through the large arteries rapidly at high pressures, but when it reaches the small capillaries the pressure and rate of flow decrease (**Figure 50.13C**). When you place your thumb over the opening of a garden hose, the pressure in the hose increases, which in turn increases the velocity of the water spraying out. But keep in mind that the arteries branch into many arterioles, which give rise to a huge number of capillaries. Even though each capillary has a diameter so small that red blood cells must pass through in single file, there are so many capillaries that their total cross-sectional area is much greater than that of any other class of vessels. As a result, all the capillaries together have a much greater capacity for blood than do the arterioles. Returning to our garden hose analogy, if we connected the hose to large number of lawn sprinklers, the pressure and flow in each sprinkler would be low.

Capillary walls consist of a single layer of endothelial cells (**Figure 50.14**). Capillaries are permeable to water, some ions, and some small molecules but not to large molecules such as proteins. At the arterial (high pressure) end, blood pressure squeezes water and small solutes out through spaces between the cells of the capillary walls into the surrounding intercellular space.

Why don't water and small-molecular-weight solutes collect in the intercellular spaces? How is the blood volume maintained if fluid is continuously leaking out of the capillaries?

Capillary Flow: A Tight Squeeze
Life10e.com/mc50.1

50.15 Starling's Forces Starling's model explains how blood volume is maintained in the capillary beds. (A) When blood pressure is greater than osmotic pressure, fluid leaves the capillaries; when blood pressure falls below osmotic pressure, fluid returns to the capillaries. (B) The balance of these two forces changes over the capillary bed as blood pressure falls.

An answer to this question was put forth more than 100 years ago by the physiologist E. H. Starling. Starling suggested that water movement across capillary walls is a result of two opposing forces, which are now known as **Starling's forces**:

- Blood pressure squeezes water and small solutes out of the capillaries.
- Osmotic pressure pulls water back into the capillaries.

Blood pressure is high at the arterial end of a capillary bed and steadily drops as blood moves toward the venous end (**Figure 50.15**). The osmotic pressure is due to the large protein molecules that cannot leave the capillaries, and it is relatively constant along the capillaries. As long as the blood pressure is above the osmotic pressure, fluid leaves the capillaries. At the venule end of most capillaries, blood pressure falls below the osmotic pressure, so fluid returns to the capillaries. The actual numbers for a normal capillary bed in a resting person suggest that there would be a *slight* net loss of fluid to the intercellular spaces. This loss, about 4 liters per day, percolates between cells as the interstitial fluid before it returns to the venous blood via the lymphatic system, which we will discuss later in this chapter.

Several observations support Starling's model. In people with severe liver disease or protein starvation, a fall in blood protein concentration leads to an accumulation of fluid in the extracellular

spaces, which results in tissue swelling, or **edema**. Edema is also characteristic of the inflammation response accompanying tissue damage or allergic responses (see **Figure 42.5**). **Histamine**, a mediator of inflammation released by certain white blood cells, increases capillary permeability and relaxes the smooth muscles of the arterioles, raising blood pressure in the capillaries and leading to fluid leakage into tissues.

A few situations are not explained by Starling's hypothesis. During strenuous exercise, the blood pressure in the arterioles serving the muscles rises substantially but does not result in edema. In birds, the blood pressure in arterioles is much higher than in mammals, and the osmotic pressure is lower. If edema is not a chronic problem in exercising muscles and in birds, what is missing from Starling's model?

Recent research suggests that bicarbonate ions (HCO_3^-) in the blood plasma contribute significantly to the osmotic attraction that draws water back into the capillaries. The CO_2 produced by cellular metabolism diffuses into the endothelial cells lining the capillaries, where it is converted into HCO_3^- and released into the plasma. When an individual is at rest, the increasing HCO_3^- concentration can cause the osmotic pressure of the blood at the venous end to be 30 mm Hg higher than at the arterial end, and during strenuous exercise this difference can be much higher. Thus it appears that CO_2 and HCO_3^- are major factors that pull water back into the capillaries.

All capillaries are permeable to O_2 , CO_2 , and small ions. Lipid-soluble substances readily pass through the capillary walls. Water and small solutes pass through spaces in the capillary wall, and in some cases through holes called **fenestrations**. These less selective capillaries are found in the digestive tract, where nutrients are absorbed, and in the kidneys, where wastes are filtered. The capillary walls also contain transporters that can facilitate the passage of specific molecules, such as glucose and lactate. Overall, permeability varies widely in different capillary beds—an important consideration in the design and delivery of drugs.

The capillaries of the brain are a special case, being rather impermeable and wrapped by glia. Not much can pass through them other than lipid-soluble substances (including alcohol and anesthetics). This high selectivity of brain capillaries is known as the **blood-brain barrier**. Even in the brain, however, there are specific regions where the capillaries are more permeable, enabling the brain to detect non-lipid-soluble hormones.

Blood flows back to the heart through veins

The pressure of the blood flowing from capillaries to venules is extremely low and is insufficient to propel blood back to the heart. The walls of veins are more expandable than the walls of arteries, and blood tends to accumulate in veins. As much as 60 percent of your total blood volume may be in your veins when you are resting. Because of their high capacity to stretch and store blood, veins are called capacitance vessels.

Blood flow through veins that are above the level of the heart is assisted by gravity. Below the level of the heart, however, venous return is against gravity. The most important force propelling blood from these regions is the squeezing of the veins by the contractions of surrounding skeletal muscles.

50.16 One-Way Flow Veins have valves that prevent blood from flowing backward, and contractions of skeletal muscle help move blood toward the heart.

As muscles contract, the vessels are compressed and blood is squeezed through them. Blood flow may be temporarily obstructed during a prolonged muscle contraction, but when muscles relax, blood is free to move again. One-way valves in the veins of the extremities prevent backflow of blood. Thus whenever a vein is squeezed, blood is propelled forward toward the heart (**Figure 50.16**).

In a resting person, gravity causes blood accumulation in the veins of the lower body and exerts backpressure on the capillary beds. This backpressure shifts the balance between blood pressure and osmotic pressure, causing increased loss of fluid to the intercellular spaces. That is why your feet swell during a long airline flight.

Because of the one-way valves in the veins of the legs, the contractions of leg muscles act as auxiliary vascular pumps when an animal walks or runs and facilitate the return of blood to the heart from the lower body. As a greater volume of blood is returned to the heart, the heart contracts more forcefully and its pumping action is enhanced. The heartbeat gets stronger because of a property of cardiac muscle cells described by the **Frank-Starling law**: if the cardiac muscle cells are stretched, as they are when the volume of returning blood increases, they contract more forcefully.

The actions of breathing also help return venous blood to the heart. The muscles involved in inhalation create negative pressure that pulls air into the lungs (see **Figure 49.11**), and this negative pressure also pulls blood toward the chest, increasing venous return to the right atrium. In addition, some of the largest veins closest to the heart contain smooth muscle that contracts at the onset of exercise. Contraction of veins can rapidly increase venous return and stimulate the heart in accord with the Frank-Starling law, increasing cardiac output.

Lymphatic vessels return interstitial fluid to the blood

The interstitial fluid contains water and small molecules, but no red blood cells, and less protein than found in plasma. A separate system of vessels—the **lymphatic system**—returns interstitial fluid to the blood. Each capillary bed contains at least one blind-ended lymph capillary.

Once it enters the lymphatic vessels, the interstitial fluid is called **lymph**. Fine lymphatic capillaries merge into progressively larger vessels and ultimately into two lymphatic vessels—the **thoracic ducts**—that empty into large veins at the base of the neck (see **Figure 42.1**). The left thoracic duct carries most of the lymph from the lower part of the body and is much larger than the right thoracic duct. Lymphatic vessels, like veins, have one-way valves that keep the lymph flowing toward the thoracic duct. Therefore lymph, like blood, is propelled toward the heart by skeletal muscle contractions and breathing movements. Lymph nodes along the major lymphatic vessels are a major site of lymphocyte production and of the phagocytic action that removes microorganisms and other foreign materials from the circulation (see **Section 42.1**).

Vascular disease is a killer

As mentioned at the start of this chapter, cardiovascular disease is responsible for about one-fourth of all deaths each year in the United States, and the same is true for Europe. The immediate cause of most of these deaths is not a defect in heart muscle as in athletes, but is heart attack or stroke—both of which are usually the end result of a disease called **atherosclerosis** (“hardening of the arteries”) that begins many years before symptoms are detected.

Healthy arteries have a smooth internal lining of endothelial cells (**Figure 50.17A**) that can be damaged by chronic high blood pressure, smoking, a high-fat diet, or microorganisms. Deposits called **plaque** begin to form at sites of endothelial damage. First, the damaged endothelial cells attract certain white blood cells to the site. These cells are then joined by smooth muscle cells migrating from the deeper layers of the arterial wall. Lipids, especially cholesterol, are deposited in these cells, so that the developing plaque becomes fatty. Fibrous connective tissue made by the invading smooth muscle cells in the plaque, along with deposits of calcium, make the artery wall less elastic—hence “hardening of the arteries.” The growing plaque deposit narrows the artery and causes turbulence in the blood flow. Blood platelets stick to the plaque (see **Figure 50.12**) and initiate formation of an intravascular blood clot, a **thrombus**, which can block the artery (**Figure 50.17B**).

50.17 Atherosclerotic Plaque (A) A healthy, clear artery. (B) An atherosclerotic artery, clogged with plaque and a thrombus.

The blood supply to the heart muscle flows through the **coronary arteries**, which are highly susceptible to atherosclerosis. As these arteries narrow, blood flow to the heart muscle decreases, causing the symptoms of chest pain and shortness of breath during mild exertion. A person with atherosclerosis is at high risk of forming a thrombus in a coronary artery. This condition, called **coronary thrombosis**, can totally block the vessel, causing a **myocardial infarction** (heart attack).

A piece of a thrombus that breaks loose, called an **embolus**, is likely to travel to and become lodged in a vessel of smaller diameter, blocking its flow (an **embolism**). Arteries already narrowed by plaque formation are likely places for an embolism. An embolism in an artery in the brain causes the cells fed by that artery to die. This event is a **stroke**. The specific damage resulting from a stroke, such as memory loss, speech impairment, or paralysis, depends on the location of the blocked artery.

Important risk factors for developing atherosclerosis are your genetic predisposition and your age. Environmental risk factors also play a large role, however. These include high-fat and high-cholesterol diets, smoking, and a sedentary lifestyle. Certain untreated medical conditions such as hypertension (high blood pressure), obesity, and diabetes are also risk factors for atherosclerosis. For those who have a genetic predisposition to atherosclerosis, it is even more important to minimize environmental risk factors. Changes in diet and behavior and treatment of predisposing medical conditions can prevent and reverse early atherosclerosis and help fend off this silent killer.

RECAP 50.4

Blood is a fluid tissue with cellular components that play roles in transport of respiratory gases, immune system function, and blood clotting. The properties of the arteries, arterioles, capillaries, venules, and veins reflect their functions. Exchanges between the blood and interstitial fluids occur in the smallest of those vessels, the capillaries.

- How are the structural differences among the various classes of vessels related to their functions? [See pp. 1039–1040 and Figure 50.13](#)
- Why are arterioles called resistance vessels and veins called capacitance vessels? [See p. 1039 and p. 1041](#)
- What factors control the movement of fluids between the vascular and extravascular spaces? [See pp. 1040–1041 and Figures 50.14 and 50.15](#)
- What propels blood from the lower part of the body back to the heart? [See pp. 1041–1042 and Figure 50.16](#)

Every tissue in the body requires an adequate flow of oxygen-saturated blood. Blood flow depends on the maintenance of an appropriate blood pressure, and the distribution of blood flow throughout the body depends on control of the resistance in the blood vessels supplying different tissues.

50.5 How Is the Circulatory System Controlled and Regulated?

When we investigate how a physiological process is regulated, we start by identifying the critical components of that process, how they can be controlled, and the information used to govern that control. Because blood flow depends on pressure, we can identify the pressure in the aorta as a critical variable of the circulatory system. The pressure in the aorta oscillates between systole and diastole, so we define our variable as the mean arterial pressure (MAP). MAP is determined by the cardiac output (CO) and the resistance to flow in the blood vessels, or total peripheral resistance (TPR):

$$\text{MAP} = \text{CO} \times \text{TPR}$$

Since CO is equal to the heart rate (HR) times how much blood the heart pumps with each beat (stroke volume [SV]), the critical relationships can be expressed as:

$$\text{MAP} = \text{HR} \times \text{SV} \times \text{TPR}$$

HR, SV, and TPR are controlled by neural and hormonal mechanisms at both the local and systemic levels. At the local level, each tissue controls its own blood flow through autoregulatory mechanisms that cause the arterioles supplying that tissue to constrict or dilate.

The collective autoregulatory actions in the capillary beds in all tissues of the body determine TPR and therefore MAP. If many arterioles suddenly dilate, TPR goes down and MAP falls. If many arterioles constrict, TPR goes up and MAP goes up. Changes in MAP provide information about changing needs of the body. In addition, as blood flows through capillary beds, its composition changes—its CO_2 content goes up and its O_2

content goes down. Thus blood composition also provides information the body uses to regulate the circulatory system.

The nervous and endocrine systems respond to changes in MAP and blood composition by changing breathing rate, heart rate, stroke volume, and peripheral resistance to match the metabolic needs of the body.

Go to Animated Tutorial 50.2
Blood Pressure and Heart Rate Regulation
Life10e.com/at50.2

Autoregulation matches local blood flow to local need

The amount of blood that flows through a capillary bed is controlled by the smooth muscle of the arteries and arterioles feeding that bed. **Figure 50.18** illustrates the flow of blood in a typical capillary bed. Blood flows into the bed from an arteriole. Smooth muscle “cuffs,” or **precapillary sphincters**, on the arteriole can shut off the supply of blood to the capillary bed. When the precapillary sphincters are relaxed and the arteriole is open, the arterial blood pressure pushes blood into the capillaries.

Autoregulation depends on the sensitivity of the smooth muscle to its local chemical environment. Low O_2 concentrations and high CO_2 concentrations cause the smooth muscle to relax, thus increasing the supply of blood, which brings in more O_2 and carries away CO_2 —a response known as hyperemia, which means “excess blood.” Increases in other by-products of metabolism, such as lactic acid, hydrogen ions, potassium, and adenosine (all of which increase in exercising muscle), also promote hyperemia. Hence activities that increase the metabolism of a tissue also induce hyperemia in that tissue.

Arterial pressure is regulated by hormonal and neural mechanisms

Control and regulation of the circulatory system begins with the local autoregulatory mechanisms that alter the resistance of arteries and arterioles feeding capillary beds. The demands of the capillary beds influence MAP and blood composition. Both of these provide information for the control of endocrine and neural responses that act to return blood pressure and composition to normal. Thus circulatory functions are matched to the regional and overall needs of the body.

Arteries and arterioles are innervated by the autonomic nervous system, particularly the sympathetic division. The sympathetic postganglionic neurotransmitter norepinephrine binds to receptors in smooth muscle in blood vessels in the gut and other tissues not essential for “fight or flight” and causes these vessels to constrict, resulting in reduced blood flow through them and an elevation in MAP. As we discussed earlier in this chapter, increased sympathetic activity increases heart rate, and by increasing the strength of the cardiac muscle contraction, it also increases stroke volume.

Hormones also play a role in regulating arterial pressure. Epinephrine has actions similar to those of norepinephrine and is released from the adrenal medulla during massive sympathetic activation stimulated by a fall in arterial pressure or by activation of the fight-or-flight response to a dangerous threat. Another hormone, **angiotensin**, is produced when blood pressure in the kidneys falls (**Figure 50.19**). These hormones influence arterioles located in peripheral tissues (extremities) or in tissues whose functions need not be maintained continuously (such as the digestive system). By reducing blood flow in those arterioles, the hormones increase central blood pressure and blood flow to essential organs such as the heart, brain, and kidneys.

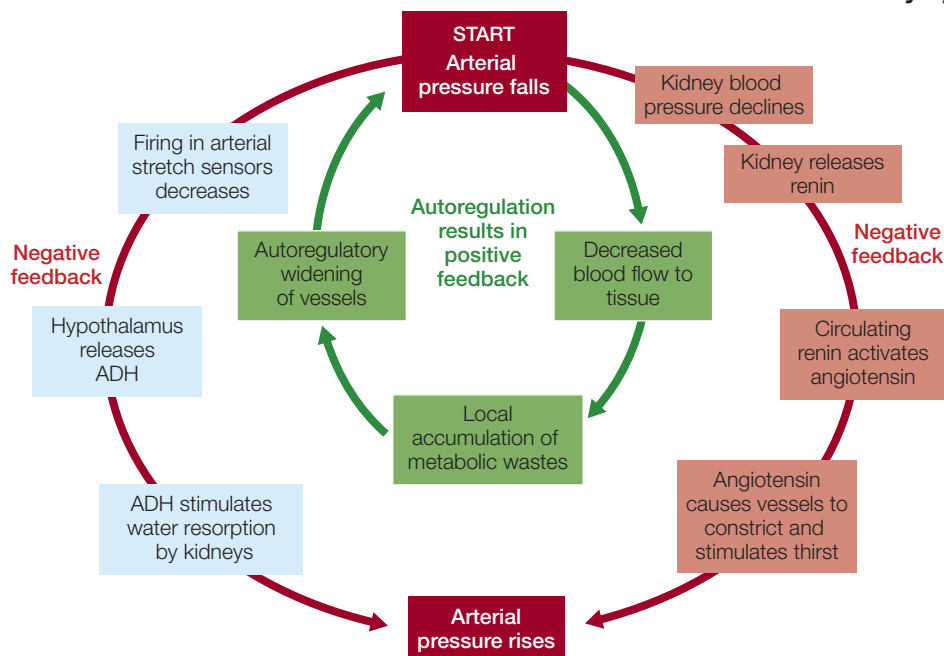

The autonomic nervous system activity that controls heart rate and constriction of blood vessels originates in a cardiovascular control center in the medulla. Many inputs converge on this central integrative network and influence the commands it issues via parasympathetic and sympathetic nerves (**Figure 50.20**). Of special importance is incoming information about changes in blood pressure and composition from both **baroreceptors** (stretch receptors) and chemoreceptors in the walls of the large arteries leading to the brain—the aorta and the carotid arteries.

Increased activity in baroreceptors of the large arteries signals rising blood pressure and inhibits sympathetic nervous system signaling to arteries and arterioles while increasing parasympathetic signaling to the heart’s pacemaker. As a result, the heart slows and arterioles in peripheral tissues dilate, reducing blood pressure. If pressure in the large arteries falls, the activity of the baroreceptors decreases, stimulating sympathetic output to the arteries and arterioles while reducing parasympathetic output to the heart’s pacemaker. As a result, the heart beats faster and the arterioles in peripheral tissues constrict, increasing blood pressure.

Another hormone that helps stabilize blood pressure is antidiuretic hormone (ADH, also called vasopressin), which is secreted by the posterior pituitary in response to a fall in the activity of the baroreceptors, signaling a fall in arterial pressure. ADH causes the kidneys to resorb more water and thereby

50.18 Local Control of Blood Flow Low O_2 concentrations or high levels of metabolic by-products cause the smooth muscle of the arteries and arterioles to relax, thus increasing the supply of blood to the capillary bed.

50.19 Control of Blood Pressure through Local and Systemic Mechanisms A drop in arterial pressure reduces blood flow to tissues, resulting in local accumulation of metabolic wastes. This change in the extracellular environment stimulates autoregulatory opening of the arteries. A fall in central blood pressure is prevented by negative feedback mechanisms (including the release of antidiuretic hormone, ADH) that constrict arteries in less essential tissues and stimulate maintenance of blood volume and blood pressure.

maintain blood volume and increase blood pressure (see Section 52.6). Increased activity of the baroreceptors inhibits the release of ADH, and as a result the kidneys excrete more water, reducing blood volume and contributing to a fall in arterial pressure (see Figure 50.19).

Other information that causes the cardiovascular control center to increase heart rate and blood pressure comes from chemoreceptors in the medulla, aorta, and the carotid arteries. As we discussed in Section 49.5, the medullary chemosensors are activated by increases in arterial CO_2 levels, and the carotid and aortic bodies are activated by falls in arterial O_2 levels. Chemosensors send signals to the cardiovascular regulatory center as well as to the respiratory regulatory center.

RECAP 50.5

The delivery of blood to tissues is controlled locally by autoregulatory mechanisms that dilate or constrict arterioles. These local actions are translated into alterations in central blood pressure and composition that are detected by neural and hormonal mechanisms, which then mediate corrective cardiovascular adjustments.

- How do autoregulatory changes in blood flow to capillary beds result in adjustments to MAP? **See p. 1044 and Figure 50.18**
- What are the roles of hormones in regulating blood pressure? **See p. 1044 and Figure 50.19**
- Describe the role of baroreceptors and chemoreceptors in regulating blood pressure. **See pp. 1044–1045 and Figure 50.20**

50.20 Regulating Cardiac Output The autonomic nervous system controls heart rate in response to information about blood pressure and blood composition originating in baroreceptors and chemoreceptors shown at the bottom of the figure. Information from these sensors goes to the cardiovascular control center in the medulla, where it is integrated with other information. The medullary center generates responses in the sympathetic and parasympathetic nervous systems that control cardiac output.

How can the same mutation-based heart condition be fatal to an athlete but innocuous in most other people?

ANSWER

The mutation responsible for the condition described in the opening story encodes a contractile protein necessary for the pumping action of cardiac muscle. The mutant form of this protein renders the heart less efficient at pumping blood, and the heart compensates by getting larger. In most people, the heart enlarges enough to meet their needs without causing other problems. High-performing athletes, however, regularly engage in heavy exercise that places huge demands on their hearts,

and in athletes with this mutation heart enlargement can be excessive. Eventually thickening of the ventricular walls, especially those of the left ventricle, can disrupt the electrical impulses that coordinate contractions of the heart muscle. When heavy demand is placed on such an enlarged heart, muscle fiber contractions can suddenly become uncoordinated or blocked, rendering the heart incapable of pumping blood.

CHAPTER SUMMARY 50

50.1 Why Do Animals Need a Circulatory System?

- The metabolic needs of the cells of many small animals are met by direct exchange of materials with the external medium. The metabolic needs of the cells of larger animals are met by a **circulatory system** that transports nutrients, respiratory gases, and metabolic wastes throughout the body.
- In **open circulatory systems**, extracellular fluid leaves vessels and percolates through tissues. In **closed circulatory systems**, the blood is contained in a system of vessels. Closed circulatory systems have the ability to selectively direct blood, hormones, and nutrients to specific tissues. **Review Figure 50.1**

50.2 How Have Vertebrate Circulatory Systems Evolved?

- The circulatory system of vertebrates consists of a heart and a closed system of vessels containing blood that is separate from the interstitial fluid. **Arteries** and **arterioles** carry blood from the heart; **capillaries** are the site of exchange between blood and interstitial fluid; **venules** and **veins** carry blood back to the heart.
- The vertebrate circulatory system evolved from a single circuit in fishes to partially or completely separate pulmonary and systemic circuits in amphibians, reptiles, and mammals.
- In the single-circuit system of fishes, blood flow is unidirectional and is propelled by one-way valves between the **sinus venosus** and the **atrium**, between the atrium and the **ventricle**, and between the ventricle and the **bulbus arteriosus**.
- In birds and mammals, blood circulates through two completely separate circuits. The **pulmonary circuit** transports blood between the heart and lungs, and the **systemic circuit** transports oxygen-rich blood between the heart and tissues. **See ACTIVITY 50.1**

50.3 How Does the Mammalian Heart Function?

- The mammalian heart has four chambers. Valves in the heart prevent the backflow of blood. **Review Figure 50.2, ACTIVITY 50.2**
- The **cardiac cycle** has two phases: **systole**, in which the ventricles contract, and **diastole**, in which the ventricles relax. The sequential heart sounds (“lub-dup”) are made by the closing of the heart valves. **Review Figure 50.3, ANIMATED TUTORIAL 50.1**

- Blood pressure can be measured using a sphygmomanometer and a stethoscope. **Review Figure 50.4**
- **Pacemaker cells** of the sinoatrial node set the heart rate as a result of the properties of their ion channels. The autonomic nervous system controls heart rate: sympathetic activity increases heart rate, and parasympathetic activity decreases it by altering the rate of depolarization of the pacemaker cell resting membrane potentials following the termination of systole. **Review Figures 50.5, 50.6**
- The **sinoatrial node** controls the cardiac cycle by initiating a wave of depolarization in the atria, which is conducted to the ventricles through a system consisting of the **atrioventricular node**, **bundle of His**, and **Purkinje fibers**. **Review Figure 50.7**
- Sustained contraction of ventricular muscle cells is due to long-duration action potentials that are generated by voltage-gated Na^+ and Ca^{2+} channels. **Review Figures 50.8, Figure 50.9**
- An **electrocardiogram (ECG or EKG)** records electrical events associated with the contraction and relaxation of the cardiac muscles. **Review Figure 50.10**

50.4 What Are the Properties of Blood and Blood Vessels?

- Blood consists of a **plasma** portion (water, salts, and proteins) and a cellular portion (**erythrocytes** or red blood cells, platelets, and white blood cells). All of the cellular components are produced from stem cells in the bone marrow. **Review Figure 50.11**
- Erythrocytes transport oxygen. Their production in the bone marrow is stimulated by **erythropoietin**, which is produced in response to **hypoxia** (low oxygen levels) in the tissues.
- **Platelets**, along with circulating proteins, are involved in **blood clotting**, which results in a meshwork of **fibrin** threads that help seal damaged vessels. **Review Figure 50.12**
- Abundant smooth muscle cells allow vessels to change their diameter, altering their resistance and thus blood flow. Arteries have elastic fibers that enable them to withstand high pressures. **Review Figure 50.13, ACTIVITY 50.3**
- Capillary beds are the site of exchange of materials between blood and tissue fluid.
- **Starling’s forces** suggest that blood volume is maintained in the capillary beds by an exchange of fluids driven by both blood pressure and osmotic pressure. **Review Figure 50.15**

continued

- An accumulation of fluid in the extracellular spaces leads to **edema**. Bicarbonate ions in the blood plasma contribute to the osmotic forces that draw water back into capillaries.
- The ability of a specific molecule to cross a capillary wall depends on the architecture of the capillary, the type of substance, and the concentration gradient between the blood and the tissue fluid.
- Veins have a high capacity for storing blood. Aided by gravity, by contractions of skeletal muscle, and by the actions of breathing, they return blood to the heart. **Review Figure 50.16**
- The **Frank–Starling law** describes forces that increase cardiac output, such as stretch of the cardiac muscles cells caused by increased venous return.
- The **lymphatic system** returns the interstitial fluid to the blood.

50.5

How Is the Circulatory System Controlled and Regulated?

- Blood flow through capillary beds is controlled by local **auto-regulatory mechanisms**, hormones, and the autonomic nervous system. **Review Figure 50.18, ANIMATED TUTORIAL 50.2**
- Blood pressure is controlled in part by the hormones ADH and **angiotensin**, which stimulate contraction of blood vessels. **Review Figure 50.19**
- Heart rate is controlled by the autonomic nervous system, which responds to information about blood pressure and blood composition that is integrated by regulatory centers in the medulla. **Review Figure 50.20**

CHAPTER REVIEW

REMEMBERING

1. Which statement about vertebrate circulatory systems is *not* true?
 - a. In fish, oxygenated blood from the gills returns to the heart through the left atrium.
 - b. In mammals, deoxygenated blood leaves the heart through the pulmonary artery.
 - c. In amphibians, deoxygenated blood enters the heart through the right atrium.
 - d. In reptiles, the blood in the pulmonary artery has a lower oxygen content than the blood in the aorta.
 - e. In birds, the pressure in the aorta is higher than the pressure in the pulmonary artery.
2. Which statement about the human heart is true?
 - a. The walls of the right ventricle are thicker than the walls of the left ventricle.
 - b. Blood flowing through atrioventricular valves is always deoxygenated blood.
 - c. The second heart sound is due to the closing of the aortic valve.
 - d. Blood returns to the heart from the lungs in the vena cava.
 - e. During systole, the aortic valve is open and the pulmonary valve is closed.
3. The pacemaker action potentials in the heart
 - a. are due to opposing actions of norepinephrine and acetylcholine.
 - b. are generated by the bundle of His.
 - c. depend on the gap junctions between the cells that make up the atria and those that make up the ventricles.
 - d. are due to spontaneous depolarization of the plasma membranes of modified cardiac muscle cells.
 - e. reflect large depolarizations of membrane potential due to opening of voltage-gated Na⁺ channels.
4. Blood velocity through capillaries is slow because
 - a. much blood volume is lost from the capillaries.
 - b. the pressure in venules is high.
 - c. the total cross-sectional area of capillaries is larger than

that of arterioles.

- d. the osmotic pressure in capillaries is very high.
- e. erythrocytes must pass through in single file.

5. Autoregulation of blood flow to a tissue is due to
 - a. sympathetic innervation.
 - b. the release of ADH by the hypothalamus.
 - c. increased activity of baroreceptors.
 - d. chemoreceptors in the aorta and the carotid arteries.
 - e. the effect of the local chemical environment on arterioles.

UNDERSTANDING & APPLYING

6. At the beginning of a race, cardiac output increases immediately before there is any change in blood O₂ or CO₂ concentrations. Explain two factors that contribute to this effect. Include the Frank–Starling law in your answer.
7. Is there a time in the mammalian cardiac cycle when all four heart valves are open? Explain.
8. A sudden and massive loss of blood results in a decrease in blood pressure. Describe several mechanisms that help return blood pressure to normal and how they do so.

ANALYZING & EVALUATING

9. The hearts of most mammals stop beating when their temperature falls more than a few degrees below 20°C, but the hearts of hibernating mammals can beat at 0°C. What adaptations of cardiac muscle might explain this capacity of the hearts of hibernators?
10. You can describe the cycle of events in a ventricle of the heart by a graph that plots the pressure in the ventricle on the *y* axis and the volume of blood in the ventricle on the *x* axis. Draw such a graph for a left ventricle using maximum and minimum pressures of 125 and 25 mm Hg and maximum and minimum ventricular volumes of 130 and 60 ml. Where would the heart sounds be on this graph? How would the graph differ for the left and the right ventricles?

Nutrition, Digestion, and Absorption

CHAPTER OUTLINE

- 51.1** What Do Animals Require from Food?
- 51.2** How Do Animals Ingest and Digest Food?
- 51.3** How Does the Vertebrate Gastrointestinal System Function?
- 51.4** How Is the Flow of Nutrients Controlled and Regulated?

FOR THOUSANDS of years the Pima of southwestern North America were hunters and gatherers who supplemented their diet with subsistence agriculture. Their environment was arid, so they developed sophisticated irrigation systems; even so, they frequently encountered drought and subsequent starvation. Today most individuals of the ethnic Pima population in North America are clinically obese. In fact, as a population they are one of the heaviest in the world.

With obesity come related health problems such as diabetes, high blood pressure, and heart disease. Diabetes incidence in the Pima is seven times the national average; two-thirds of adults over the age of 40 are diabetic. Moreover, diabetes is occurring in younger individuals than ever before. What has caused such a radical health change in an entire population? Two interacting factors are involved: genetics and lifestyle.

Geneticists hypothesize that recurring episodes of starvation produce strong selective pressure for “thrifty genes”—particular alleles of the genes involved in digestion, absorption, and energy storage that result in greater-than-average efficiency in converting food into energy reserves, such as fat. Thrifty genes would carry a strong selective advantage when food is scarce. The Pima display a “thrifty” phenotype. They have low resting metabolic rates and convert food into fat readily. For many Pima, consuming a standard amount of glucose causes their insulin levels to rise three times higher than it does in Americans of European ancestry. Insulin is the hormone that facilitates conversion of dietary sugar into fat.

Efficiency Genes The Pima are an example of a human population that repeatedly experienced periods of severe food deprivation. These historic occurrences may have imposed selection for genes that improve the efficiency of managing the energy obtained from food. With modern diets and lifestyles, these “efficiency genes” can contribute to obesity.

The other factor in the Pima obesity epidemic is an abrupt change in their traditional lifestyle. Instead of eating their traditional diet, the Pima now eat a high-calorie, high-fat Western diet, and they engage in less physical activity than their ancestors did.

Another population of Pima lives in the Sierra Madre of northern Mexico. Genetically they are the same as the Arizona population. However, they eat traditional foods and live a traditional lifestyle that involves much physical activity. Whereas the Arizona Pima engage in an average of only 2 hours of physical work per week, the Mexico Pima average 23 hours per week. Obesity and diabetes are not prevalent among the Mexico Pima.

A high-calorie diet and sedentary lifestyle affect not just the Pima but contribute to the overall increase in obesity throughout the U.S. population. Researchers are studying the Pima to learn more about the genetics of obesity and related pathologies.

Are there genes that predispose a person to obesity?

See answer on p. 1068.

(A)

51.1 Heterotrophs Get Energy from Autotrophs (A) Herbivores get their energy directly from autotrophs. The large herbivores of the African grasslands must consume huge amounts of plant matter

(B)

to fulfill their nutritional needs. (B) A carnivore's energy is indirectly obtained from autotrophs, since the energy stored in a prey animal was originally obtained from autotrophs.

51.1

What Do Animals Require from Food?

Animals are **heterotrophs**—they derive their nutrition from eating other organisms. In contrast, **autotrophs** (most plants, some bacteria, some archaea, and some protists) can use solar energy or inorganic chemical energy to synthesize all of their components. Directly and indirectly, heterotrophs take advantage of—indeed, depend on—the organic synthesis carried out by autotrophs and have evolved an enormous diversity of adaptations to exploit this resource (**Figure 51.1**). In this section we will describe how animals use food, be it plants or other animals, to obtain energy and building blocks of complex molecules. We will also consider the need for special mineral nutrients and organic molecules and the diseases that result when they are lacking in the diet.

Energy needs and expenditures can be measured

Energy—the capacity to do work—comes in different forms, including electric, heat, chemical, and nuclear energy. As discussed in Chapter 8, a calorie (note the small *c*) is a unit of heat energy; specifically, it is the amount of heat necessary to raise the temperature of 1 gram of water 1°C. Because this is such a tiny amount of energy, physiologists commonly use the **kilo-calorie (kcal)** as a unit of measure (1 kcal = 1,000 calories). Nutritionists also use the kilocalorie as a standard unit of energy, but they traditionally refer to it as the **Calorie (Cal)**, which is capitalized to distinguish it from the single calorie.

Just about any food container you pick up in the U.S. carries the label “Nutrition Facts” that includes the item “Calories.” How do Calories (or kcal) relate to the discussion in Chapter 9 about how energy in the chemical bonds of food molecules is transferred to the high-energy phosphate bonds of adenosine triphosphate (ATP) and is then used to do cellular work? And why do we use heat energy as a measure of nutrition?

The reason is found in the laws of thermodynamics, which tell us that energy cannot be created or destroyed, but can be converted from one form to another (see Section 8.1). However, every energy conversion is inefficient and a large portion of the original energy always ends up as heat. Whether we are using the energy in glucose to make ATP or are using that ATP to power muscle contraction or ion transport, most of the available chemical energy is lost as heat. The bottom line is that if an animal is not growing, not doing any external work, and not changing its body temperature, the heat it loses to the environment is a measure of its total energy expenditure, or metabolism.

An animal's energy needs must be met by the ingestion, digestion, and assimilation of food. The basal energy expenditure of a human is 1,300 to 1,500 Cal/day for an adult female and 1,600 to 1,800 Cal/day for an adult male. Physical activity adds to this basal energy requirement. For a person doing sedentary work, about 30 percent of the Calories expended are used for skeletal muscle activity; for a person doing heavy physical labor, more than 95 percent of caloric expenditure is for skeletal muscle activity.

The components of food that provide energy are fats, carbohydrates, and proteins. Fats yield 9.5 Cal/gram, carbohydrates 4.2 Cal/gram, and proteins about 4.1 Cal/gram. **Figure 51.2** shows some equivalencies of food, energy, and energy consumption.

Even though the units calorie, kilocalorie, and Calorie remain in popular use, most scientists now use the International System of Units (ISU). In this system the basic unit of energy is the joule: 1 joule = 0.239 calories, and the measure of energy use is 1 joule/second = 1 watt. You are familiar with light bulb ratings, so think about that when you convert kcal/day into watts. The 1,700 Cal/day energy expenditure of the average man converts to 82 watts (note that a watt includes the time dimension, so it is a rate of energy use).

Thus it is possible to quantify the caloric value of any food an animal eats. It is also possible to quantify the caloric

51.2 Food Energy and How We Use It The energy contained in several common food items is shown at the left. The graphs indicate about how long it would take a person with a basal energy requirement of about 1,800 Cal/day to use the equivalent amount of energy while resting, walking, or jogging.

expenditure of any activity or behavior an animal performs. By comparing calories consumed with calories expended, we can construct **energy budgets** that allow ecologists and evolutionary biologists to apply a cost–benefit analysis to feeding behavior, as we will explain in Section 53.4.

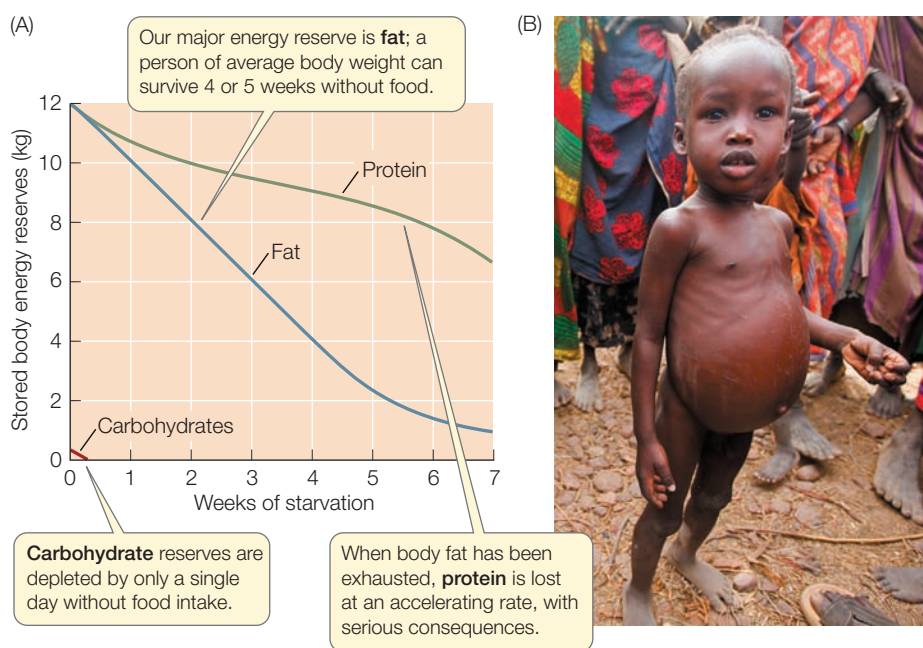

Sources of energy can be stored in the body

Although the cells of the body use energy continuously, most animals do not eat continuously and so must store fuel molecules that can be released as needed between meals. Carbohydrates are stored in liver and muscle cells as glycogen, but the total glycogen stored represents only about a day's basal energy requirement. Fat is the most important form of stored energy in the bodies of animals. Not only does fat have more energy per gram than glycogen, but it can be stored with little associated water, making it more compact. Migrating birds store energy as fat to fuel their long flights; if they had to store the same amount of energy as glycogen, they would be too heavy to fly. Proteins are not used as energy storage compounds, although the body's structural protein can be metabolized as an energy source of last resort.

51.3 The Course of Starvation (A) In a person subjected to undernutrition, the body's energy reserves are eventually depleted. (B) The swollen abdomen, face, hands, and feet of this girl are due to edema. Along with her spindly limbs, these are symptoms of kwashiorkor, a syndrome resulting from the body breaking down blood proteins and muscle tissue to fuel metabolism.

If an animal takes in too little food to meet its energy requirements, it must start metabolizing some of the molecules of its own body. This “self-consumption” begins with the energy storage compounds glycogen and fat. Once fat reserves are seriously depleted, the body increases its metabolism of proteins for energy (**Figure 51.3A**). The first proteins to be sacrificed are those of the blood plasma. The loss of plasma proteins decreases the osmotic concentration of the plasma, resulting in increased loss of fluid from the blood to the interstitial spaces (edema; see Section 50.4). Accumulation of fluid in the extremities and abdomen is the classic sign of kwashiorkor, a disease caused by chronic protein deficiency (**Figure 51.3B**). Continued protein loss damages the body's organs, leading eventually to death.

When an animal consistently takes in more food than it needs to meet its energy requirements, the excess nutrients are stored as increased body mass. First glycogen reserves build

up; then additional dietary carbohydrates, fats, and proteins are converted to body fat. In some species, such as hibernators, seasonal overnutrition is an important adaptation for surviving periods when food is not available. In humans, however, overnutrition can be a serious health hazard, increasing the risk of high blood pressure, heart attack, diabetes, and other disorders, as seen in the Pima discussed in the chapter opener.

Food provides carbon skeletons for biosynthesis

Every animal must take in certain organic molecules that it cannot synthesize for itself but needs to form the building blocks of its own complex organic molecules. The acetyl group ($\text{CH}_3\text{CO}-$) is one such required building block, supplying the **carbon skeleton** of larger organic molecules (Figure 51.4). Animals cannot synthesize acetyl groups from carbon, oxygen, and hydrogen molecules but must obtain them from food. Acetyl groups can be derived from the metabolism of almost any food, but they originate in plants.

Acetyl groups are never in short supply for an adequately nourished animal. However, some groups supplying carbon skeletons can be deficient in an animal's diet even if caloric intake is adequate. One such group includes certain amino acids, the building blocks of proteins. Animals can synthesize some of their own amino acids using carbon skeletons from acetyl or other groups and transferring to them amino groups ($-\text{NH}_2$) derived from other amino acids. However, most animals cannot synthesize all the amino acids they need and thus must obtain certain **essential amino acids** from food. If an animal does not take in enough of even one of its essential amino acids, its protein synthesis is impaired and its capacity to maintain enzymatic and transport functions is challenged.

Essential amino acids vary by species. Most researchers agree that adult humans must obtain eight essential amino acids from their food: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. All eight are available in milk, eggs, meat, and soybean products, but most plant foods do not contain adequate quantities of all eight, so a strict vegetarian diet carries a risk of protein malnutrition.

A **complementary diet** of plant foods, however, supplies all eight essential amino acids (Figure 51.5). In general, grains (such as rice, wheat, and corn) are complemented by legumes (such as beans and peas). Long before the chemical basis for complementarity was understood, societies with little access to meat developed complementary diets. Many Central and South American peoples traditionally eat beans with corn, and the native peoples of North America complemented their beans with squash.

Human infants are thought to require four additional amino acids in their diets: histidine, tyrosine, cysteine, and arginine. Also, some amino acids are required by individuals with certain metabolic disorders who cannot synthesize them adequately. For example, individuals with the genetic disease phenylketonuria lack the enzyme for converting phenylalanine to tyrosine (see Section 15.2) and must obtain tyrosine from their diets. They must keep their dietary intake of phenylalanine low to prevent its accumulation to toxic levels.

Why are dietary proteins completely digested to their constituent amino acids before being used by the body? Wouldn't it be more energy-efficient to reuse some dietary proteins

51.5 A Strategy for Vegetarians By combining cereal grains with legumes, an adult vegetarian can obtain all eight essential amino acids.

directly? There are several reasons why ingested proteins are not used “as is”:

- Macromolecules such as proteins are not readily absorbed by the cells of the gut, but their constituent monomers (such as amino acids) are readily absorbed.
- Protein structure and function are highly species-specific. A protein that functions optimally in one species might not function well in another.
- Foreign proteins entering the body directly from the gut would be recognized as invaders and would be attacked by the immune system.

Humans can synthesize almost all the lipids required by the body using acetyl groups obtained from food (see Figure 51.4), but we must have a dietary source of certain **essential fatty acids**—notably, linoleic acid—that we cannot synthesize. Linoleic acid is needed by mammals to synthesize other unsaturated fatty acids, such as arachidonic acid, which is a component

of several signaling molecules, including prostaglandins. Essential fatty acids are also necessary components of membrane phospholipids. A deficiency of linoleic acid can lead to problems such as infertility and impaired lactation, but because it is commonly present in vegetable oils, a deficiency is unlikely in an adequately nourished individual.

Animals need mineral elements for a variety of functions

Table 51.1 lists the principal mineral elements that animals require. Elements required in large amounts are called **macronutrients**; those required in only tiny amounts (generally less than 100 mg/day) are called **micronutrients**. Some micronutrients are required in such minute amounts that deficiencies are never observed, but they are nevertheless essential elements.

Calcium is an example of a macronutrient. It is the fifth most abundant element in the body; a 70-kg person contains about 1.2 kg of calcium. Calcium phosphate is the principal structural

TABLE 51.1 Mineral Elements Required by Animals

Element	Source in Human Diet	Major Functions
MACRONUTRIENTS		
Calcium (Ca)	Dairy foods, eggs, green leafy vegetables, whole grains, legumes, nuts, meat	Found in bones and teeth; blood clotting; nerve and muscle action; enzyme activation
Chlorine (Cl)	Table salt (NaCl), meat, eggs, vegetables, dairy foods	Water balance; digestion (as HCl); principal negative ion in extracellular fluid
Magnesium (Mg)	Green vegetables, meat, whole grains, nuts, milk, legumes	Required by many enzymes; found in bones and teeth
Phosphorus (P)	Dairy, eggs, meat, whole grains, legumes, nuts	Component of nucleic acids, ATP, and phospholipids; bone formation; buffers; metabolism of sugars
Potassium (K)	Meat, whole grains, fruits, vegetables	Nerve and muscle action; protein synthesis; principal positive ion in cells
Sodium (Na)	Table salt, dairy foods, meat, eggs	Nerve and muscle action; water balance; principal positive ion in extracellular fluid
Sulfur (S)	Meat, eggs, dairy foods, nuts, legumes	Found in proteins and coenzymes; detoxification of harmful substances
MICRONUTRIENTS		
Chromium (Cr)	Meat, dairy, whole grains, legumes, yeast	Glucose metabolism
Cobalt (Co)	Meat, tap water	Found in vitamin B ₁₂ ; formation of red blood cells
Copper (Cu)	Liver, meat, fish, shellfish, legumes, whole grains, nuts	Found in active site of many redox enzymes and electron carriers; production of hemoglobin; bone formation
Fluorine (F)	Most water supplies	Found in teeth; helps prevent tooth decay
Iodine (I)	Fish, shellfish, iodized salt	Found in thyroid hormones
Iron (Fe)	Liver, meat, green vegetables, eggs, whole grains, legumes, nuts	Found in active sites of many redox enzymes and electron carriers, hemoglobin, and myoglobin
Manganese (Mn)	Organ meats, whole grains, legumes, nuts, tea, coffee	Activates many enzymes
Molybdenum (Mo)	Organ meats, dairy, whole grains, green vegetables, legumes	Found in some enzymes
Selenium (Se)	Meat, seafood, whole grains, eggs, milk, garlic	Fat metabolism
Zinc (Zn)	Liver, fish, shellfish, and many other foods	Found in some enzymes and some transcription factors; insulin physiology

material in bones and teeth. Muscle contraction, neural function, and many other intracellular functions in animals require calcium ions (Ca^{2+}). The turnover of calcium in the extracellular fluid is high, as bones are constantly being remodeled and calcium is constantly entering and leaving cells. Calcium is lost from the body in urine, sweat, and feces, so it must be replaced regularly. Adult humans require 800 to 1,000 mg of calcium per day in their diet.

Iron is an example of a micronutrient. It is found throughout the body because it is the oxygen-binding atom in hemoglobin and myoglobin and is a component of enzymes in the electron transport chain. Nevertheless, the total amount of iron in a 70-kg person is only about 4 grams, and since iron is recycled efficiently in the body and is not lost in the urine, we require only about 15 mg per day in our food. Despite the small amount required, insufficient iron is the most common mineral nutrient deficiency in the world today. Iron deficiency leads to anemia, a condition that renders individuals weak and tired all the time.

Go to Activity 51.1 Mineral Elements Required by Animals
[Life10e.com/ac51.1](https://openstax.org/r/life10e-ac51.1)

Animals must obtain vitamins from food

Like essential amino acids and fatty acids, **vitamins** are carbon compounds that an animal requires for growth and metabolism

but cannot synthesize for itself. They are required in very small amounts compared with the essential amino acids and fatty acids that are incorporated into large body structures. Most vitamins function as coenzymes or parts of coenzymes.

The list of vitamins varies from species to species. Most mammals, for example, can make their own ascorbic acid. Primates (including humans) cannot, so for primates, ascorbic acid is a vitamin—vitamin C. If we do not get vitamin C in our food, we develop scurvy, a disease characterized by bleeding gums, loss of teeth, subcutaneous hemorrhages, and slow wound healing. Scurvy was a frequently fatal problem for sailors on long voyages until late in the eighteenth century, when a Scottish physician, James Lind, discovered that the disease could be prevented if the sailors ate fresh greens and citrus fruit. The British Admiralty made limes standard provisions for its ships (and British sailors have been called “limeys” ever since). When the active ingredient in limes was isolated, it was named ascorbic (“without scurvy”) acid.

Humans require 13 vitamins; these are divided into two groups, water-soluble and fat-soluble (**Table 51.2**). When water-soluble vitamins are ingested in excess of bodily needs, they are simply eliminated in the urine. (This is the fate of much of the large doses of vitamin C that people take.) Fat-soluble vitamins, however, can accumulate in body fat and may build up to toxic levels in the liver if taken in excess.

TABLE 51.2
Vitamins in the Human Diet

Vitamin	Source	Function	Deficiency Symptoms
WATER-SOLUBLE			
B ₁ (thiamin)	Liver, legumes, whole grains	Coenzyme in cellular respiration	Beriberi, loss of appetite, fatigue
B ₂ (riboflavin)	Dairy, meat, eggs, green leafy vegetables	Coenzyme in FAD	Lesions in corners of mouth, eye irritation, skin disorders
Niacin	Meat, fowl, liver, yeast	Coenzyme in NAD and NADP	Pellagra, skin disorders, diarrhea, mental disorders
B ₆ (pyridoxine)	Liver, whole grains, dairy foods	Coenzyme in amino acid metabolism	Anemia, slow growth, skin problems, convulsions
Pantothenic acid	Liver, eggs, yeast	Found in acetyl CoA	Adrenal problems, reproductive problems
Biotin	Liver, yeast, bacteria in gut	Found in coenzymes	Skin problems, loss of hair
B ₁₂ (cobalamin)	Liver, meat, dairy foods, eggs	Formation of nucleic acids, proteins, red blood cells	Pernicious anemia
Folic acid	Vegetables, eggs, liver, whole grains	Coenzyme in formation of heme and nucleotides	Anemia
C (ascorbic acid)	Citrus fruits, tomatoes, potatoes	Formation of connective tissues; antioxidant	Scurvy, slow healing, poor bone growth
FAT-SOLUBLE			
A (retinol)	Fruits, vegetables, liver, dairy	Found in visual pigments	Night blindness
D (calciferol)	Fortified milk, fish oils, sunshine	Absorption of calcium and phosphate	Rickets
E (tocopherol)	Meat, dairy foods, whole grains	Muscle maintenance, antioxidant	Anemia
K (menadione)	Intestinal bacteria, liver	Blood clotting	Blood clotting problems

The fat-soluble vitamin D (calciferol), which is essential for absorbing and metabolizing calcium, is a special case because the body can synthesize it. (As noted in Section 41.4, vitamin D is by definition a hormone.) Certain lipids present in the human body can be converted into vitamin D by the action of ultraviolet light on the skin. Thus vitamin D must be obtained in the diet by individuals with inadequate exposure to the sun.

The need for vitamin D may have been an important factor in the evolution of skin color. For humans living in equatorial and low latitudes, dark skin pigmentation is adaptive, as it is a protection against the damaging effects of ultraviolet radiation. These peoples generally expose extensive areas of skin to the sun on a regular basis, so their skin synthesizes adequate amounts of vitamin D. Most races that adapted to life in the higher latitudes lost this dark skin pigmentation, probably because lighter skin facilitates vitamin D production in the relatively small areas of skin exposed to sunlight during the short days of winter. The dark-skinned Inuit peoples of the Arctic are an exception to the correlation between latitude and skin pigmentation, but the Inuit obtain ample vitamin D from the large amounts of animal fat (especially whale blubber) and fish oils in their diet.

Nutrient deficiencies result in diseases

The lack of any essential nutrient in the diet produces a state of **malnutrition**, and chronic malnutrition leads to a characteristic **deficiency disease** (see Table 51.2). We have discussed kwashi-orkor (protein deficiency) and scurvy (vitamin C deficiency). Another deficiency disease, beriberi, was directly involved in the discovery of vitamins.

Beriberi, which means “extreme weakness,” became prevalent in Asia in the nineteenth century when it became standard practice to mill rice to a white polish and discard the hulls present in brown rice. A critical observation was that chickens and pigeons developed beriberi-like symptoms when they were fed only polished rice. In 1912 Casimir Funk, a Polish scientist working in England, cured pigeons of beriberi by feeding them discarded rice hulls.

At the time of Funk’s discovery, all diseases were thought either to be caused by microorganisms or to be inherited. Funk suggested that beriberi and some other diseases are dietary in origin and result from deficiencies in specific substances. Funk coined the term “vitamines” from “vital amines” because he mistakenly thought that all these substances vital for life were compounds with amino groups. In 1926 thiamin (vitamin B₁)—the substance lost in the rice milling process—was the first vitamin to be isolated in pure form.

Deficiency diseases can also result from an inability to absorb or process an essential nutrient even if it is present in the diet. Vitamin B₁₂ (cobalamin), for example, is present in all foods of animal origin. Since plants neither use nor produce vitamin B₁₂, a strictly vegetarian diet (not supplemented with dairy products or vitamin pills) can lead to a B₁₂ deficiency disease called pernicious anemia, characterized by a failure of red blood cells to mature. The most common cause of pernicious

anemia, however, is not a lack of vitamin B₁₂ in the diet but an inability to absorb it. Normally cells in the stomach lining secrete a peptide called intrinsic factor, which binds to vitamin B₁₂ and makes it absorbable by the small intestine. Conditions that damage the stomach lining, such as alcoholism or gastritis, can thus lead to pernicious anemia.

Inadequate mineral nutrition can also lead to deficiency diseases. Examples are hypothyroidism and goiter resulting from iodine deficiency (see Section 41.4), and anemia resulting from iron deficiency. Iodine deficiency is almost unheard of in the developed world because we add iodide to salt. However, it is still a major health problem in large segments of the human population.

RECAP 51.1

As heterotrophs, animals must obtain the energy and molecular building blocks for biosynthesis from their food. Energy can come from the metabolism of carbohydrates, fats, and proteins. Molecular building blocks include carbon skeletons, vitamins, and minerals.

- Explain the different roles of dietary proteins, carbohydrates, and fats in producing metabolic energy. **See p. 1050 and Figure 51.3**
- Explain the nutritional roles of an essential carbon skeleton, a micronutrient, and a macronutrient. **See pp. 1051–1052, Figure 51.4, and Table 51.1**
- Why should fat-soluble vitamins not be taken in excess? **See p. 1053**

We have surveyed the essential elements of nutrition in animals. Next we will look at various methods and adaptations by which animals obtain the food they need, and the mechanisms they use to extract nutrients from their food.

51.2

How Do Animals Ingest and Digest Food?

Heterotrophic organisms can be classified by how they acquire their nutrition. **Saprobies** (also called saprotrophs) are organisms—most of which are either protists or fungi—that absorb nutrients from dead organic matter. **Detritivores or decomposers**, such as earthworms and crabs, actively feed on dead organic material. Animals that feed on living organisms are **predators**: **herbivores** prey on plants, **carnivores** prey on animals, and **omnivores** prey on both. **Filter feeders**, such as clams and blue whales, prey on small organisms by filtering them from the aquatic environment. **Fluid feeders** include mosquitoes, aphids, leeches, and hummingbirds. The anatomical adaptations that enable a species to exploit a particular source of nutrition are usually obvious, but physiological and biochemical adaptations are also important, although less obvious.

The food of herbivores is often low in energy and hard to digest

Most vegetation is coarse, difficult to break down, and has low energy content. Therefore herbivores spend a great deal of time feeding and processing their food. Many have striking

adaptations for feeding, such as the trunk (a flexible, gripping nose) of the elephant or the huge bill of the fruit-eating toucan, which can be half as long as its body. Many types of grinding, rasping, cutting, and shredding mouthparts have evolved in invertebrates for ingesting plant material, and the teeth of herbivorous vertebrates have been shaped by selection to tear, crush, and grind coarse plant matter.

The digestive processes of herbivores can also be quite specialized. An example is the koala, which almost exclusively eats leaves of eucalyptus trees. These leaves are very fibrous, low in usable energy and protein, and high in toxic chemicals. The koala has strong jaws for grinding the leaves, a very long gut for fermenting them, enzymes in its liver for detoxifying chemicals in the leaves, and a low metabolic rate (i.e., it expends little energy) to compensate for low energy intake.

Carnivores must find, capture, and kill prey

The predatory behaviors of many carnivores are legendary—the hunting skills of hawks, wolves, and tigers, for example. Carnivores have evolved stealth, speed, power, large jaws, sharp teeth, and strong gripping appendages. They also have evolved remarkable means of detecting prey. Bats use echolocation, pit vipers sense infrared radiation from the warm bodies of their prey, and certain fish detect electric fields created in the water by their prey. There are many fascinating examples of adaptations for capturing prey, such as the immobilizing venom of many snakes, the long sticky tongues of chameleons, and the webs of spiders.

Some predators digest their prey externally. For example, a spider injects its insect prey with digestive enzymes and then

sucks out the liquefied contents, leaving behind the empty exoskeletons frequently seen in old spider webs. The majority of animals, however, digest their food internally. For many, the process of digestion begins with the physical breaking down of the food items by the teeth.

Vertebrate species have distinctive teeth

Teeth are adapted for the acquisition and initial processing of specific types of foods. Because they are among the hardest structures of the body, an animal's teeth remain in the environment long after it dies. Paleontologists use teeth to identify animals that lived in the distant past and to deduce their feeding behavior.

All mammalian teeth have the same general, three-layered structure (**Figure 51.6A**). An extremely hard material called **enamel**, composed principally of calcium phosphate, covers the crown of the tooth. Both the crown and root contain a layer of bony material called **dentine**, inside of which is a **pulp cavity** containing blood vessels, nerves, and the cells that produce the dentine.

There is a great deal of homology in the dentition of mammals, but the shapes and organization of mammalian teeth are adaptations to different diets (**Figure 51.6B**). In general, incisors are used for cutting, chopping, and gnawing; canines are used for stabbing, gripping, and ripping; and molars and premolars (the cheek teeth) are used for shearing, crushing, and grinding. The highly varied diet of humans is reflected in our multipurpose set of teeth, as is common among omnivores.

Current methods make it possible to analyze residues derived from food in and on tooth enamel of prehistoric animals.

51.6 Mammalian Teeth (A) A mammalian tooth has three layers: enamel, dentine, and a pulp cavity. (B) The teeth of different mammalian species are specialized for different diets. This illustration depicts the teeth of the lower jaw, viewed from above.

Go to Activity 51.3 Mammalian Teeth Life10e.com/ac51.3

Such analysis of some hominin fossils (*Paranthropus boisei*; see Figure 33.34) from South Africa has revealed that they were predominantly grass eaters. What was the evidence for this conclusion? Tropical grasses are C_4 plants (see Section 10.4), whereas leafy trees that produce fruits and nuts are C_3 plants. The carbon residues on the *Paranthropus* teeth were those produced by C_4 plants, presumably grasses and sedges.

Digestion usually begins in a body cavity

Animals take food into a body cavity that is continuous with the outside environment. They secrete digestive enzymes into that cavity, and the enzymes break down the food into nutrient molecules that can be absorbed by the cells lining the cavity.

The simplest digestive system is found in the simplest animals, the sponges. Water flows from the environment through the body of the sponge in water channels, and individual cells capture food particles from the water (see Figure 31.2B). A slightly more specialized digestive system is a **gastrovascular cavity**, which connects to the outside world through a single opening. Cnidarians, such as jellyfish, capture prey using stinging nematocysts and use their tentacles to cram the prey into their gastrovascular cavity. Enzymes in the gastrovascular cavity partially digest the prey. Cells lining the cavity take in small food particles by endocytosis. The vesicles created by endocytosis then fuse with lysosomes containing digestive enzymes, and intracellular digestion completes the breakdown of the food. Nutrients are released to the cytoplasm as the vesicles break down.

Tubular guts have an opening at each end

The guts of most animals are tubular: a **mouth** takes in food; molecules are digested and absorbed throughout the length of the gut; and solid digestive wastes are eliminated through an **anus**. Different regions in the tubular gut are specialized for particular functions (Figure 51.7). These functions must be coordinated so they occur in the proper sequence and at rates that maximize the efficiency of digestion and absorption of nutrients.

At the anterior end of the gut is the mouth cavity where food can be fragmented by teeth (in many vertebrates), by a **radula** (in snails), or by **mandibles** (in many arthropods). In most birds, food is ground by small stones in an early, muscular portion of the gut called the **gizzard**. Some animals, such as snakes, simply ingest whole prey with little or no fragmentation. **Stomachs** and **crops** are storage chambers that enable animals to ingest relatively large amounts of food when it is available, and then digest it gradually. In these storage chambers, food may be further fragmented and mixed, and in most vertebrates it is an important site of digestion. Food delivered into the next section of the gut, the **intestine**, is in small particles, well mixed, and usually partially digested.

Most digestion occurs in the intestine, and nutrients, water, and ions are absorbed across its walls. Glands secrete digestive enzymes into the intestine, and other enzymes are produced and secreted by cells lining the intestine. The final segment of the intestine recovers water and ions and stores undigested

51.7 Compartments for Digestion and Absorption Most invertebrates and all vertebrates have a tubular gut that begins with a mouth, which takes in food, and ends in an anus, which eliminates wastes. Between these two structures are specialized regions for digestion and nutrient absorption; the structures in these regions are adapted to different diets and vary from species to species.

wastes, or **feces**, so they can be released to the environment at an appropriate time or place. A muscular **rectum** near the anus assists in expelling feces.

Endosymbiotic bacteria colonize the intestines. These bacteria obtain their nutrition from the food passing through the host's gut while contributing to the host's digestive processes. Members of the leech genus *Hirudo*, for example, produce no enzymes that can digest the proteins in the blood they suck from vertebrates; instead they depend on bacteria to perform this service. The resulting amino acids are subsequently used by both the leech and the bacteria. The microorganisms in

51.8 Intestinal Surface Area and Nutrient Absorption Maximizing the surface area of the gut increases an animal's ability to absorb nutrients.

the human gut are called the “forgotten organ” because they provide important services in digestion, prevent the establishment of harmful microorganisms, and even produce some vitamins (vitamin K and biotin). This forgotten organ is huge. It is estimated that the human body consists of 10^{13} cells, but our guts contain probably ten times that number of unicellular organisms representing at least 500 different species (see Figure 26.21).

In many animals, the parts of the gut that absorb nutrients have greater surface areas than would be expected of a simple tube. The simplest way to increase the surface area of a tube without changing its diameter is to produce an infolding. Such an infolding of the gut, called a typhlosole, is seen in earthworms (Figure 51.8A). Sharks, which have large stomachs but short intestines, have a unique adaptation called a spiral valve (Figure 51.8B). The lower region of the intestine is enlarged and has an internal structure that forces the food to pass through it in a spiral fashion (like going down a spiral staircase). The walls of the spiral present a large surface area for absorption of nutrients. This spiral passage, however, will not accommodate large chunks of food or undigestible matter, so food remains

in the stomach for a long time to be broken down, and some larger, undigestible items (such as pieces of surfboard) do not leave the stomach except by regurgitation.

In humans, as in most other vertebrates, the wall of the intestine is highly folded, with the individual folds bearing legions of tiny fingerlike projections called **villi** (Figure 51.8C). The cells that line the surfaces of the villi, in turn, have microscopic projections called **microvilli**. The microvilli give the intestine an enormous internal surface area for absorbing nutrients.

Digestive enzymes break down complex food molecules

Protein, carbohydrate, and fat macromolecules are broken down into their simplest monomeric units by hydrolytic enzymes produced at different locations in the digestive tract. Many are secreted into the lumen of the gut, and others remain associated with the membranes of the microvilli. All of these enzymes cleave the chemical bonds of macromolecules through hydrolysis, a reaction that adds a water molecule (see Figure 3.4B). Digestive enzymes are classified according to the substances they hydrolyze: **proteases** break the bonds between

adjacent amino acids in proteins; **carbohydrases** hydrolyze carbohydrates; **peptidases** break down peptides; **lipases**, fats; and **nucleases**, nucleic acids.

RECAP 51.2

Heterotrophs have diverse adaptations for acquiring food. Once captured or ingested, food is digested extracellularly by secreted enzymes to release nutrients, which are absorbed into the animal's body, usually via a tubular gut.

- Why do herbivores typically spend a great deal of their time feeding? [See p. 1054–1055](#)
- What characteristics of tooth structure distinguish herbivores, carnivores, and omnivores? [See p. 1055 and Figure 51.6.](#)
- What are three adaptations of the human gut that increase its surface area for absorption of nutrients? [See p. 1057 and Figure 51.8](#)

Once ingested by an animal, food may be fragmented and moved into the gut for digestion by hydrolytic enzymes. The processes of digestion release nutrients that are absorbed into the animal's body. Next we will focus on how those processes occur in vertebrates.

51.3

How Does the Vertebrate Gastrointestinal System Function?

Digestion in vertebrates occurs in the gastrointestinal system, which includes a tubular gut running from mouth to anus and several accessory structures that produce secretions that play important roles in digestion ([Figure 51.9](#)). In this section we will consider three important processes of this system: the movement of food through it, the sequential steps of digestion, and the absorption of nutrients. We will use as our primary example a typical vertebrate, the human.

The vertebrate gut consists of concentric tissue layers

The tissues of the vertebrate gut are arranged in concentric layers that have a similar organization throughout its length ([Figure 51.10](#)). Starting in the internal cavity, or **lumen**, the first layer is the **mucosa**, which consists of delicate epithelial cells with underlying connective tissue. Some cells of this mucosal epithelium secrete mucus to lubricate and protect the walls of the gut; some secrete digestive enzymes; and some secrete hormones. Mucosal epithelial cells in the stomach secrete hydrochloric acid and, as we noted in Section 51.1, some secrete intrinsic factor to aid the absorption of vitamin B₁₂. In some regions of the gut, nutrients are absorbed by mucosal epithelial cells. The apical plasma membranes of these absorptive cells have microvilli that increase the surface area over which absorption can take place (see [Figure 51.8C](#)).

At the base of the mucosa are smooth muscle cells that move the mucosa to improve contact with gut contents, and just under the mucosa is the submucosal tissue layer. Here we find

51.9 The Human Digestive System Different compartments in the long tubular gut specialize in digesting food, absorbing nutrients, and storing and expelling wastes. Accessory organs contribute secretions containing enzymes and other molecules.

Go to Activity 51.4 The Human Digestive System
Life10e.com/ac51.4

the blood and lymph vessels that carry absorbed nutrients to the rest of the body. The **submucosa** also contains a network of nerves; the neurons in this network have sensory functions (responsible for stomach aches) and also control various secretory functions of the gut.

External to the submucosa are two layers of smooth muscle responsible for the large movements of the gut. Innermost is the circular muscle layer, with its cells oriented around the gut. Outermost is the longitudinal muscle layer, with its cells oriented along the length of the gut (see [Figure 51.10](#)). The circular muscles constrict the gut, and the longitudinal muscles shorten it. Between the two layers of smooth muscle is another nerve network that controls and coordinates the movements of the gut. The coordinated activity of the two smooth muscle layers mixes the content of the gut and moves it continuously toward the rectum. The stomach has a third layer of smooth muscle that is closest to the lumen. The orientation of its fibers is oblique to the longitudinal and circular layers. This third layer is important in generating churning motions of the stomach that mix the food and digestive juices.

Go to Media Clip 51.1
Following Food from Mouth to Gut
Life10e.com/mc51.1

51.10 Tissue Layers of the Vertebrate Gut The organization of tissue layers is the same in all compartments of the gut, but specialized adaptations of specific tissues characterize different regions.

The nerve nets in the submucosa and between the smooth muscle layers are called the **enteric nervous system**, and they are unusual. Whereas most neurons of the peripheral nervous system either receive synapses from neurons in the central nervous system (CNS) or contribute synapses to neurons in the CNS, most of the neurons in the enteric nervous system form

synapses only with other neurons in their network. Thus they are responsible for communication within the gut. The CNS can influence activity in the enteric nervous system and receive information from it, but the gut truly has “a mind of its own.”

A tissue membrane called the **peritoneum** surrounds the gut, as it does all of the organs of the abdominal cavity as well as lining the wall of the cavity. The peritoneum includes connective and epithelial tissues that secrete a fluid that lubricates the organs so they can easily slide against each other in the body cavity.

Mechanical activity moves food through the gut and aids digestion

In humans and most other mammals, food is chewed in the mouth and mixed with saliva. Periodically the tongue pushes a bolus (mass) of the chewed food toward the throat. By making contact with the soft palate at the back of the mouth cavity, the food bolus initiates swallowing, which is a complex series of reflexes. Swallowing propels the food through the pharynx (where the mouth cavity and nasal passages join) and into the **esophagus** (food tube). To prevent food from entering the trachea (windpipe), the larynx (voice box) closes, and a flap of tissue called the **epiglottis** covers the entrance to the larynx (**Figure 51.11A**).

Once a bolus of food enters the esophagus, it is moved toward the stomach both by the force of gravity and by waves of muscle contraction called **peristalsis** (**Figure 51.11B**). The muscle of the upper region of the esophagus is striated (i.e., skeletal muscle) and is controlled by the central nervous system reflexes of swallowing. The muscles of the rest of the esophagus are smooth muscle controlled by the autonomic and enteric nervous systems.

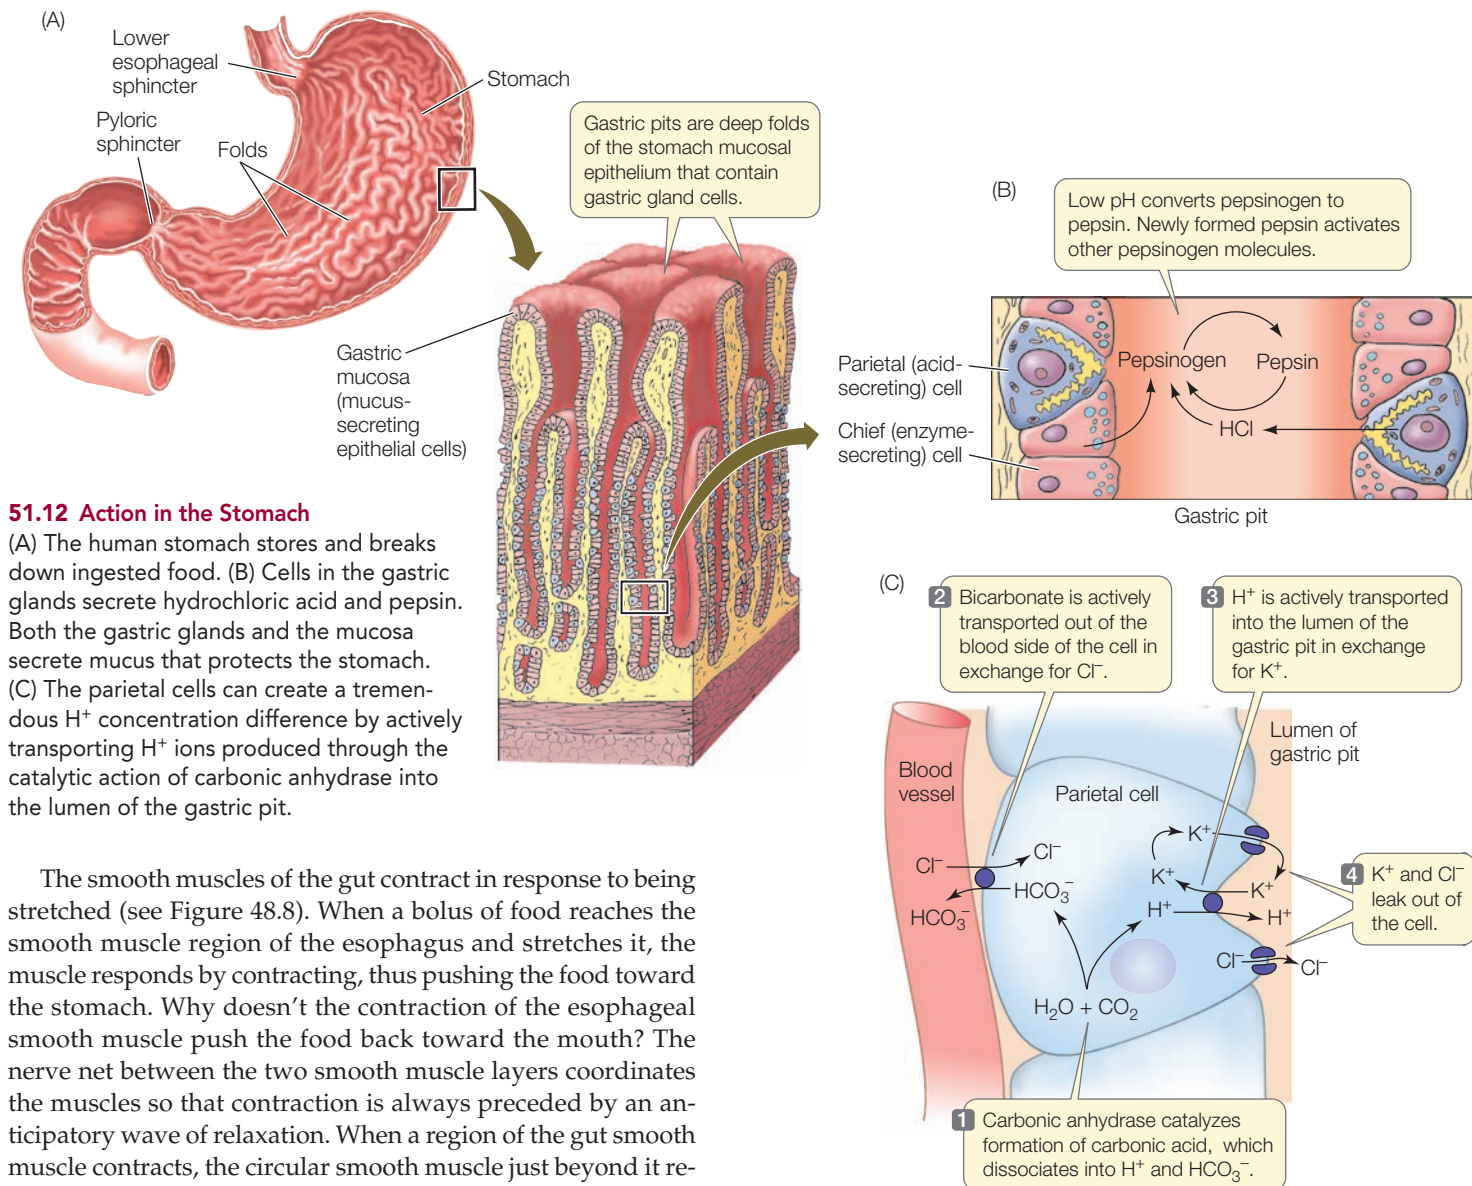

(A) Swallowing

(B) Peristalsis

51.11 Swallowing and Peristalsis (A) Food pushed to the back of the mouth triggers the swallowing reflex. (B) Once a food bolus enters the esophagus, peristalsis propels it from mouth to anus by coordinated actions of the circular and longitudinal muscle layers of the gut.

51.12 Action in the Stomach

(A) The human stomach stores and breaks down ingested food. (B) Cells in the gastric glands secrete hydrochloric acid and pepsin. Both the gastric glands and the mucosa secrete mucus that protects the stomach. (C) The parietal cells can create a tremendous H^+ concentration difference by actively transporting H^+ ions produced through the catalytic action of carbonic anhydrase into the lumen of the gastric pit.

The smooth muscles of the gut contract in response to being stretched (see Figure 48.8). When a bolus of food reaches the smooth muscle region of the esophagus and stretches it, the muscle responds by contracting, thus pushing the food toward the stomach. Why doesn't the contraction of the esophageal smooth muscle push the food back toward the mouth? The nerve net between the two smooth muscle layers coordinates the muscles so that contraction is always preceded by an anticipatory wave of relaxation. When a region of the gut smooth muscle contracts, the circular smooth muscle just beyond it relaxes while the longitudinal smooth muscle contracts, pushing the food into that area. The resulting stretch causes that circular smooth muscle to contract while the next region relaxes. In this way peristalsis moves food down the gut from the mouth to the anus.

At the junction of the esophagus and stomach is the lower esophageal **sphincter**, a thick ring of circular smooth muscle. This sphincter is normally constricted, but waves of peristalsis cause it to relax enough to let food pass from the esophagus into the stomach. Sphincter muscles are found throughout the digestive tract: the pyloric sphincter governs the passage of stomach contents into the small intestine; the ileocaecal sphincter controls the flow of food between the small and large intestines; and the anal sphincter relaxes to allow defecation.

The movements of the stomach and small intestine are not as coordinated as the peristaltic movements of the esophagus. They are referred to as **segmentation movements** because segments of the gut periodically contract but do not generate a peristaltic wave of contraction that moves the food in one direction. Segmentation movements move the content of the gut in either direction and thereby mix it with the digestive juices

and bring it in contact with the gut walls. Weak peristaltic activity in the small intestine still moves the gut content toward the large intestine.

Chemical digestion begins in the mouth and the stomach

Salivary glands secrete the enzyme amylase into the mouth where it is mixed with the food being chewed. Amylase hydrolyzes the bonds between the glucose monomers that make up carbohydrate molecules. The action of amylase is what makes a chewed piece of bread or cracker taste slightly sweet if you hold it in your mouth long enough.

A main role of the stomach is to store food so that digestion can occur more slowly than ingestion, but the stomach also secretes digestive enzymes. **Gastric pits** in the stomach walls are lined with three types of secretory cells (Figure 51.12A). **Chief cells** secrete a proteolytic enzyme, pepsin, that begins the digestion of protein. **Parietal cells** pump out H^+ ions, and the lowered pH kills most ingested microorganisms. This mix

of substances could damage the stomach walls, but the epithelial cells of the gastric mucosa secrete mucus that provides a protective coating for the walls of the gastric pits and stomach.

Chief cells actually secrete an inactive digestive enzyme, or **zymogen**, called pepsinogen. The extremely low pH of the stomach juices initiates the conversion of pepsinogen to pepsin by cleaving away a sequence of amino acids that masks the active site of the enzyme. Newly activated pepsin activates other pepsinogen molecules, creating a positive feedback process called **autocatalysis** (Figure 51.12B).

The parietal cells of the gastric pits can produce about 2 liters of hydrochloric acid (HCl) per day—enough to bring the pH of the stomach contents below 1, which is the same as battery acid and ten times more acidic than pure lemon juice. This means that across their plasma membranes, gastric pits can create a H^+ ion concentration difference of 3 million-fold. Such a feat of transport is not seen anywhere else in the body. How do the gastric pits do it? Enzymes and transporters are involved.

The enzyme carbonic anhydrase in parietal cells catalyzes the hydration of CO_2 to H_2CO_3 , which dissociates into H^+ and bicarbonate ion (HCO_3^-). An antiporter transport protein (see Figure 6.13) exchanges HCO_3^- for Cl^- on the blood side of the gastric pits, and an antiporter on the gastric pit side exchanges H^+ for K^+ (Figure 51.12C). However, this K^+ can leak out again down its concentration gradient. Thus the inward transport of K^+ acts like an endless conveyor belt moving H^+ out into the stomach lumen. Cl^- also passively leaks out of the gastric lumen side of the parietal cells to maintain electrical neutrality.

The stomach gradually releases its contents to the small intestine

Contractions of the smooth muscles in the walls of the stomach churn its contents, thoroughly mixing them with the stomach secretions. The acidic, fluid mixture of gastric juice and partly digested food in the stomach is called **chyme**. A few substances can be absorbed across the stomach wall, including alcohol (hence its rapid effects), aspirin, and caffeine, but even these substances are absorbed in rather small quantities from the stomach.

Contractions of the stomach walls push the chyme toward the bottom of the stomach. These waves of contractions cause the pyloric sphincter to relax briefly so that little squirts of the chyme can enter the small intestine. In this manner the human stomach empties itself gradually over a period of approximately 4 hours. This slow introduction of food into the small intestine enables it to work on a little material at a time.

Most chemical digestion occurs in the small intestine

In the **small intestine**, the digestion of carbohydrates and proteins continues, and the digestion of fats and absorption of nutrients begin. The small intestine takes its name from its diameter; it is in fact a very large organ, about 6 meters long in an adult human. Given its length and the folds, villi, and microvilli of its lining, its inner surface area is roughly the size of a tennis court. Across this surface the small intestine absorbs all the nutrient molecules derived from food.

51.13 Ducts of the Gallbladder and Pancreas Bile produced in the liver leaves the liver via the hepatic duct. Branching off this duct is the gallbladder, which stores bile. Below the gallbladder, the hepatic duct is called the common bile duct and is joined by the pancreatic duct before entering the duodenum.

The small intestine of humans has three sections. The initial section (about 25 cm long) is called the **duodenum** and is the site of most digestion; the **jejunum** and the **ileum** (together about 600 cm) carry out 90 percent of the absorption of nutrients (see Figure 51.9).

Digestion in the small intestine requires many specialized enzymes, as well as several other secretions. Two accessory organs that are not part of the digestive tract—the liver and the pancreas—produce many of these secretions and deliver them to the lumen of the intestine through ducts.

LIVER The liver synthesizes **bile salts** from cholesterol and secretes them as **bile**. Bile also includes other substances, such as phospholipids and bilirubin (the breakdown product of hemoglobin). Bile flows from the liver through the hepatic duct. A side branch off the hepatic duct called the cystic duct goes to the **gallbladder**, where bile is stored. Below this junction, the hepatic duct is called the common bile duct. Before it reaches the duodenum, the common bile duct is joined by the pancreatic duct (Figure 51.13).

Fat entering the duodenum stimulates cells of the duodenal epithelium to release the hormone **cholecystokinin (CCK)**, which stimulates the walls of the gallbladder to contract rhythmically. As a result, bile is squeezed out of the gallbladder and through the cystic duct to the common bile duct. A small sphincter at the junction of the common bile duct with the duodenum relaxes in response to waves of peristalsis and allows squirts of bile to enter the duodenal lumen.

To understand the role of bile in fat digestion, think of an oil-and-vinegar salad dressing. The oil, which is hydrophobic, tends to aggregate in large globules. For that reason, many salad dressings include an emulsifier—something that prevents oil droplets from aggregating. Mayonnaise, for example, is oil and vinegar with egg yolk added as an emulsifier. Bile salts emulsify fats in the chyme. One end of each bile salt molecule is lipophilic (soluble in fat), and the other end is hydrophilic (soluble in water). The lipophilic ends of bile molecules merge with the fat droplets, leaving their hydrophilic ends sticking out. As a result, bile salts prevent the fat droplets from sticking together and thereby greatly enlarge the surface area of the fats exposed to the lipases—the enzymes that digest fats. The very small fat particles that result are called **micelles** (Figure 51.14A).

(A) Digestion of fats

(B) Absorption of fats

51.14 Digesting Fats (A) Dietary fats are broken up by bile into small micelles that present a large surface area to lipases. (B) The products of fat digestion are absorbed by intestinal mucosal cells, where they are resynthesized into triglycerides and exported to lymphatic vessels.

Go to Animated Tutorial 51.1
The Digestion and Absorption of Fats
Life10e.com/at51.1

PANCREAS The **pancreas** is a large gland that lies just behind and below the stomach (see Figures 51.9 and 51.13). It is both an endocrine gland (secreting hormones into the extracellular fluid; see Section 41.1) and an exocrine gland (secreting digestive juices through the pancreatic duct to the gut lumen). The exocrine tissues of the pancreas produce a host of digestive enzymes, including lipases, amylases, proteases, and nucleases (Table 51.3). As in the stomach, the protease enzymes are released as zymogens; if proteases were not in this inactive state, they would digest the pancreas and its ducts before ever reaching the duodenum. Once in the duodenum, the zymogen trypsinogen is activated by the enzyme enterokinase (secreted by cells lining the duodenum) to produce the active protease **trypsin**. Trypsin cleaves other zymogens, releasing other proteases as well as more active trypsin.

The mixture of zymogens produced by the pancreas can be dangerous if the pancreatic duct is blocked or if the pancreas is injured by infection or physical trauma such as a blow to the abdomen. A few activated trypsin molecules can initiate a chain reaction of enzyme activity that digests the tissues of the pancreas (a condition called pancreatitis), destroying both its endocrine and exocrine functions.

The pancreas also produces a secretion rich in bicarbonate ions (HCO_3^-). Bicarbonate ions are alkaline (basic) and neutralize the acidic pH of the chyme that enters the duodenum from the stomach. Intestinal enzymes function best at a neutral or slightly alkaline pH.

TABLE 51.3
Major Digestive Enzymes of Humans

Source/Enzyme	Action
SALIVARY GLANDS	
Salivary amylase	Starch → Maltose
STOMACH	
Pepsin	Proteins → Peptides; autocatalysis
PANCREAS	
Pancreatic amylase	Starch → Maltose
Lipase	Fats → Fatty acids and glycerol
Nuclease	Nucleic acids → Nucleotides
Trypsin	Proteins → Peptides; zymogen activation
Chymotrypsin	Proteins → Peptides
Carboxypeptidase	Peptides → Shorter peptides and amino acids
SMALL INTESTINE	
Aminopeptidase	Peptides → Shorter peptides and amino acids
Dipeptidase	Dipeptides → Amino acids
Enterokinase	Trypsinogen → Trypsin
Nuclease	Nucleic acids → Nucleotides
Maltase	Maltose → Glucose
Lactase	Lactose → Galactose and glucose
Sucrase	Sucrose → Fructose and glucose

Nutrients are absorbed in the small intestine

The final step in digesting proteins and carbohydrates and absorbing their components occurs among the microvilli. Mucosal epithelial cells produce peptidases that cleave small peptides into absorbable amino acids. These epithelial cells also produce the enzymes maltase, lactase, and sucrase that cleave the common disaccharides into absorbable monosaccharides—glucose, galactose, and fructose. There is also some lipase activity for fat digestion.

Many humans stop producing the enzyme lactase in childhood and thereafter have difficulty digesting lactose (the sugar in milk). Lactose is a disaccharide and cannot be absorbed without being cleaved into its constituents, glucose and galactose. Unabsorbed lactose is metabolized by bacteria in the large intestine, causing gas, diarrhea, and abdominal cramps.

The mechanisms by which cells of the intestinal epithelium absorb nutrients and inorganic ions are diverse and include diffusion, facilitated diffusion, osmosis, active transport, and co-transport. Many inorganic ions such as sodium, calcium, and iron are actively transported by these cells. For example, active Na^+ transporters exist on the basal and lateral sides of the epithelial cells. They maintain a low concentration of Na^+ in those cells so that Na^+ can diffuse in from the chyme in the intestinal lumen. About 30 grams of Na^+ are transported this way every day, and Cl^- follows.

The transport of Na^+ and other ions is also important for water absorption because it creates an osmotic concentration gradient. At least 7 to 8 liters of water per day move through the spaces between the epithelial cells in response to this osmotic gradient. Because the water moves through *spaces* between the cells and not through the cells themselves, it can carry with it nutrients that are in solution—a transport mechanism called “solvent drag.”

Many different kinds of transport proteins exist in the epithelial cell membranes. Some, such as the transport protein for fructose, only facilitate diffusion, and that requires a concentration gradient. This mechanism works for fructose because once fructose enters the cell it is converted to glucose. Thus the concentration of fructose in the cell is always low and the concentration gradient is maintained. Transport proteins known as symporters (see Figure 6.13) exploit the concentration gradient of Na^+ between the inside and outside of the cell that is maintained by the Na^+/K^+ ATPase common to all cells. Symporters combine the transport of Na^+ and another molecule, such as glucose, galactose, or an amino acid. As Na^+ moves down its concentration gradient into the cell, the “hitchhiking” molecules are carried along with it.

The absorption of the products of fat digestion is relatively simple. Triglycerides are hydrolyzed to diglycerides, monoglycerides, and fatty acids, all of which are lipid-soluble and thus able to pass through the plasma membranes of the microvilli. In the intestinal epithelial cells, these molecules are resynthesized into triglycerides, combined with cholesterol and phospholipids, and coated with protein to form water-soluble **chylomicrons** (Figure 51.14B). Rather than enter the blood directly, chylomicrons pass into blind-ended lymph

vessels called **lacteals** that are inside each villus (see Figure 51.8C). They then flow through the lymphatic system, entering the bloodstream through the thoracic ducts at the base of the neck. After a meal rich in fats, chylomicrons can be so abundant in the blood that they give the plasma a milky appearance. Chylomicrons deliver their triglyceride and cholesterol cargo as they circulate through tissues.

The bile salts that emulsify fats are not absorbed along with the monoglycerides, diglycerides, and the fatty acids, but are shuttled back and forth between the gut contents and the microvilli. In the ileum, bile salts are actively reabsorbed and returned to the liver via the bloodstream.

Absorbed nutrients go to the liver

Blood leaving the digestive tract flows to the liver in the **hepatic portal vein**. This large vein delivers the blood to small spaces called sinusoids between groups of liver cells. These cells absorb the nutrients coming from the digestive tract and either store them or convert them to molecules the body needs. Glucose, sucrose, and fructose are used to synthesize glycogen. Amino acids are used to build proteins. Lipids from the chylomicrons are either stored as triglycerides or used to make lipoproteins, which are released by the liver and carry the triglycerides and cholesterol to other tissues (see Section 51.4).

Water and ions are absorbed in the large intestine

The motility of the small intestine gradually pushes its contents into the large intestine, or **colon**. Most of the available nutrients have been removed from the chyme that enters the colon, but it contains a lot of water and inorganic ions. Segmentation movements bring the colon’s contents into contact with its walls and promote reabsorption of ions and water, producing feces, a semisolid mass of waste products. Absorption of too much water from the colon can cause constipation. The opposite condition, diarrhea, results if too little water is absorbed; in this case, water in the colon is excreted with the feces. Excessive diarrhea caused by diseases such as cholera can produce such rapid loss of water and electrolytes that death can occur in hours.

Fecal matter is stored in the descending colon and in the rectum until defecation occurs. This is usually once a day and is preceded by strong peristaltic activity. The distension of the walls of the rectum by fecal matter initiates a parasympathetic reflex, causing the rectal muscle to contract and the internal anal sphincter to relax. In addition, there is an external anal sphincter that is under conscious control so that defecation is not entirely an involuntary act.

Herbivores rely on microorganisms to digest cellulose

As the primary component of plant cell walls, cellulose is the principal component of the food of herbivores. Most herbivores, however, cannot produce cellulases, the enzymes that break down cellulose. (Exceptions include earthworms, shipworms, and the silverfish that eat books and stored papers.) From termites to cattle, herbivores rely on microorganisms in their digestive tracts to digest cellulose.

51.15 A Ruminant's Stomach

Bison, like their relatives domestic cattle, have a specialized stomach with four compartments that enables them to obtain energy from coarse plant material through bacterial fermentation of the otherwise indigestible plant material. The bacteria themselves become an important source of nutrition.

The stomachs of **ruminants** (cud chewers) such as cattle are large, four-chambered organs that take advantage of their endosymbiotic microorganisms (**Figure 51.15**). The first two chambers, the **rumen** and the **reticulum**, are packed with microorganisms that break down cellulose by fermentation. The ruminant periodically regurgitates the contents of the rumen (the cud) into the mouth for more chewing. When swallowed again, the vegetal fibers present more surface area to the microorganisms. The microorganisms metabolize cellulose and other nutrients to simple fatty acids, which are nutrients for their host.

Enormous numbers of microorganisms leave the rumen along with the partially digested food. This mass is concentrated by water absorption in the **omasum** before it enters the true stomach, the **abomasum**, where the microorganisms are killed by secreted hydrochloric acid, digested by proteases, and passed on to the small intestine for further digestion and absorption. A cow derives more than 100 grams of protein per day from digestion of its endosymbiotic microorganisms. The rate of multiplication of microorganisms in the rumen offsets their loss, so a well-balanced, mutually beneficial relationship is maintained.

Some mammalian herbivores have a microbial fermentation chamber called a **cecum** extending from the large intestine. An example is the rabbit (see **Figure 51.7**). Since the cecum empties into the large intestine, absorption of some nutrients produced by the microorganisms is inefficient, because of the large intestine's limited surface area. Such species frequently produce two kinds of feces—ones that are pure waste and ones that contain cecal material. In a behavior known as **coprophagy**, these species reingest the cecal feces directly from the anus so they can digest and absorb the nutrients that would otherwise be lost. In humans the cecum is small and ends in the vestigial **appendix**, which serves no digestive function.

RECAP 51.3

The vertebrate gastrointestinal system is a tubular gut that is adapted to ingest food, fragment it, digest it, and absorb nutrients. Peristalsis moves food through the gut. Segmentation movements mix the gut contents. Digestion and absorption of nutrients occur mostly in the small intestine; water and ions are absorbed in the large intestine.

- What digestive functions occur in the mouth and stomach? **See p. 1060–1061 and Figure 51.12**
- How do bile salts assist in the digestion of fats? **See p. 1062 and Figure 51.14**
- Describe how symporters drive the absorption of nutrients. **See p. 1063**

The steps included in ingestion and digestion of food—from fragmentation in the mouth to the digestive processes in the gastrointestinal tract—make the nutrients in food available for absorption and ultimately for metabolism. We look next at how the processes of digestion are controlled and how nutrients are handled by the body once food has been digested.

51.4**How Is the Flow of Nutrients Controlled and Regulated?**

The vertebrate gut is an assembly line in reverse—a *disassembly line*. As with a standard assembly line, the control and coordination of the sequential processes of digestion are critical. Both neuronal and hormonal controls govern these processes. Once the products of digestion are absorbed, their availability to the cells of the body must also be controlled.

You have certainly experienced salivation at the sight or smell of food. That response is an unconscious reflex, as is

swallowing. Many such autonomic reflexes coordinate activity in different regions of the digestive tract. For example, the introduction of food into the stomach stimulates increased activity in the colon that may lead to defecation.

Neuronal messages travel from one region of the digestive tract to another in the enteric nervous system. One function of the gut's nervous system is coordinating the movement of food through the gut. Of course, this intrinsic nervous system communicates information to the CNS and receives input from the CNS, but its most important role is to coordinate actions throughout the digestive tract. In spite of this marvelous intrinsic nervous system, however, much of the control and regulation of the digestive system and nutrient management involves hormonal mechanisms.

Hormones control many digestive functions

Several hormones control the activities of the digestive tract and its accessory organs (Figure 51.16). The first hormone ever discovered came from the duodenum; it was called **secretin** because it causes the pancreas to secrete digestive juices. We now know that secretin is only one of several hormones that control pancreatic secretion; specifically, secretin stimulates the pancreas to secrete a solution rich in bicarbonate ions.

The stimulus that causes the duodenum to release secretin is low pH caused by the arrival of acidic chyme from the stomach. Similarly, the presence of fats and proteins in the chyme stimulates the release of cholecystokinin (CCK), the hormone that stimulates the gallbladder to release bile. CCK also stimulates the pancreas to release digestive enzymes. Both CCK and secretin slow the movements of the stomach, thus slowing the delivery of chyme into the small intestine and allowing more complete digestion in the duodenum.

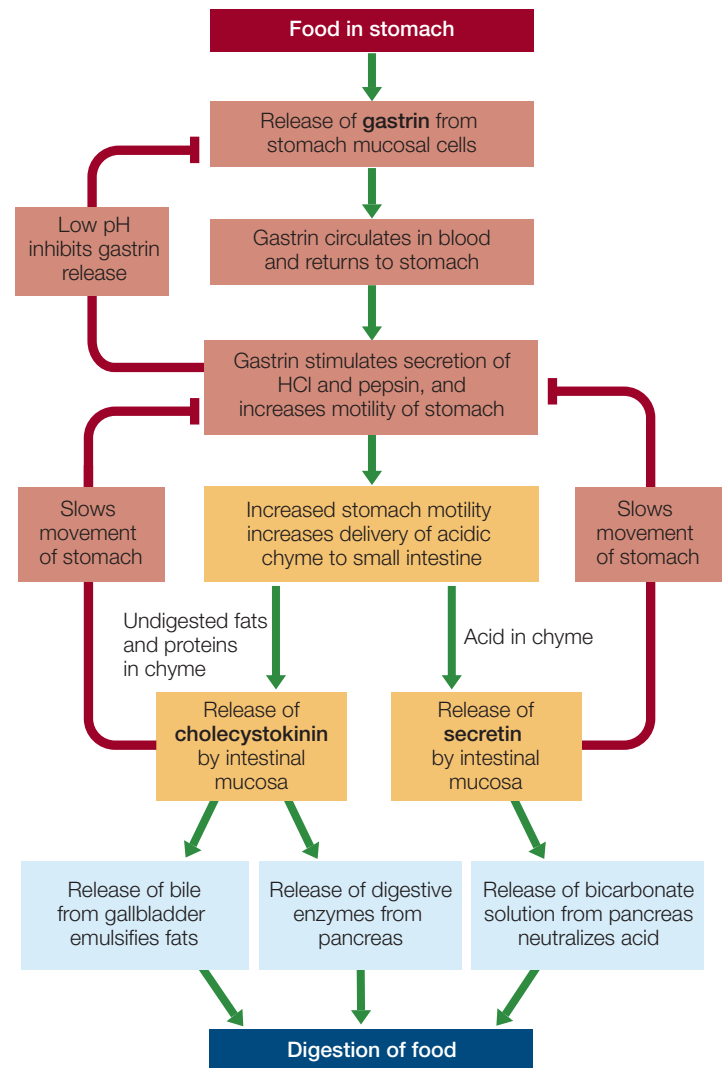

The presence of food in the stomach stimulates cells in the lower region of the stomach to secrete a hormone called **gastrin**. Gastrin returns to the stomach in the blood and stimulates the secretion of digestive juices and also the movements of the stomach. Gastrin release begins to be inhibited when the pH of the stomach contents falls below 3—an example of negative feedback.

Most animals do not eat continuously, so they can be either in an **absorptive state** (food in the gut) or in a **postabsorptive state** (no food in the gut). Nutrient requirements for energy metabolism and biosynthesis are continuous, however. Thus nutrient traffic must be controlled so that reserves accumulate in the liver, muscle, and adipose (fat) tissue while the animal is in the absorptive state and are then used efficiently during the postabsorptive state.

The liver directs the traffic of the molecules that fuel metabolism

When fuel molecules are abundant in the blood, the liver stores them in the form of glycogen and fats. The liver also synthesizes blood plasma proteins from circulating amino acids. When levels of fuel molecules in the blood decline, the liver taps its reserves and delivers nutrients into the blood.

The liver has an enormous capacity to interconvert fuel molecules. Liver cells can convert monosaccharides into either

51.16 Hormones Control Digestion The hormones gastrin, cholecystokinin, and secretin are involved in feedback loops that control the sequential processing of food in the digestive tract. Red lines indicate inhibitory actions; green lines indicate stimulatory actions.

glycogen or fats, and vice versa. The liver can also convert certain amino acids and some other molecules, such as pyruvate and lactate, into glucose—the process of gluconeogenesis (see Section 9.5). Gluconeogenesis provides an indirect pathway for exercising muscle to contribute to blood glucose levels. At high levels of aerobic activity, muscle cells break down their stores of glycogen to provide metabolic fuel (see Section 48.2). The glucose released from muscle glycogen cannot leave muscle cells as it can leave liver cells. However, when the activity of the muscle becomes anaerobic, pyruvate and lactate build up, leave the muscle cells, and enter the circulation. Circulating pyruvate and lactate are taken up by the liver and converted to glucose that can then move out of the liver cells and into the blood.

The liver is also the major controller of fat metabolism through its production of lipoproteins. A **lipoprotein** is a

particle made up of a core of hydrophobic fat and cholesterol with a covering of hydrophilic protein that allows it to be suspended in water.

LIPOPROTEINS: THE GOOD, THE BAD, AND THE UGLY Lipoproteins move fats, the most abundant fuel reserve in the body, from sites of absorption or synthesis to sites of storage, and from sites of storage to sites of use. We saw in Section 51.3 how, in the intestine, bile solves the problem of processing hydrophobic fats in an aqueous medium. The transport of fats in the circulatory system presents the same problem, and lipoproteins provide the solution.

The chylomicrons (see p. 1063) produced by the mucosal cells of the intestine are the largest lipoprotein particles in the blood. As the circulation carries chylomicrons through the liver and adipose tissue, lipoprotein lipases begin to break them down, and their triglyceride and cholesterol cargo is absorbed into the liver or fat cells.

Lipoproteins other than chylomicrons are synthesized in the liver. These lipoproteins can be classified according to their density. Fat has a low density (it floats on water) and protein has a high density, so the greater the fat-to-protein ratio in the lipoprotein, the lower its density.

- **High-density lipoproteins (HDLs)** remove cholesterol from tissues and carry it to the liver, where it can be used to synthesize bile. HDL consists of about 50% protein, 35% lipids, and 15% cholesterol. These are the “good” lipoproteins, and their levels are higher in people who exercise and are fit.
- **Low-density lipoproteins (LDLs)** transport cholesterol around the body for use in biosynthesis and for storage. LDL consists of about 25% protein, 25% lipids, and 50% cholesterol. These are the “bad” lipoproteins associated with a high risk for cardiovascular disease.
- **Very low-density lipoproteins (VLDLs)** contain mostly triglyceride fats, which they transport to fat cells in adipose tissues around the body. VLDL consists of about 2% protein, 94% lipids, and 3% cholesterol. These are the “ugly” lipoproteins, as they are associated with excessive fat deposition as well as a high risk for cardiovascular disease.

INSULIN AND GLUCAGON CONTROL FUEL METABOLISM During the absorptive state, blood glucose levels rise as carbohydrates are digested and absorbed (**Figure 51.17**). During this time, beta cells of the pancreas release the hormone **insulin**, which plays a major role in directing glucose to where it will be used or stored. The actions of insulin vary in different tissues, but they are all aimed at promoting the use of glucose for metabolic fuel and directing the excess glucose into storage as either glycogen or fat.

Glucose enters cells by diffusion. This diffusion is facilitated by transporters, but they are not active transporters—they require a concentration gradient, which is why it is important to regulate blood glucose levels so there is always an adequate glucose concentration gradient across the cell membranes.

51.17 Regulating Glucose Levels in the Blood Insulin (blue) and glucagon (brown) interactions maintain the homeostasis of circulating glucose. It is important for blood glucose to remain stable because it is the essential source of fuel for the nervous system.

Go to **Animated Tutorial 51.2**
Insulin and Glucose Regulation
Life10e.com/at51.2

There are several kinds of glucose transporters, and those in skeletal muscle and adipose tissues are normally sequestered in cytoplasmic vesicles until insulin binds its receptors on the cell surface and triggers the insertion of transporters into the plasma membrane.

Insulin plays many roles in controlling how cells use the glucose they take up from the circulation. In adipose cells, insulin inhibits lipase and promotes fat synthesis from glucose. In the liver, insulin activates an enzyme that phosphorylates glucose as it enters the liver cell so it cannot diffuse back out again, enhancing the overall diffusion of glucose into the cells. Insulin also activates the enzymes in liver cells that catalyze the synthesis of glycogen.

During the postabsorptive state, a fall in blood glucose decreases the release of insulin, and the uptake of glucose by most cells is curtailed (see Figure 51.17). To maintain blood glucose levels, liver cells break down their stored glycogen, releasing glucose into the blood. The liver and adipose tissues break down fats and supply fatty acids to the blood, and most cells preferentially use those fatty acids as their metabolic fuel. *The most important control of fuel metabolism in the postabsorptive state is the lack of insulin.*

One tissue that does not switch fuel sources when an animal is postabsorptive is the nervous system. The cells of the nervous system require a constant supply of glucose and can use other fuels only to a very limited extent. Most neurons do not require insulin to absorb glucose from the blood, but they do need an adequate glucose concentration gradient to drive the facilitated diffusion of glucose across their plasma membranes. Therefore it is critical that blood glucose levels are maintained when an animal is postabsorptive. The overall dependence of neural tissues on glucose, and their requirement for constant blood glucose levels, are the reasons it is so important for other cells of the body to shift to fat metabolism during the postabsorptive state.

The metabolism of fuel molecules during the postabsorptive state is mostly controlled by the lack of insulin, but if blood glucose falls below a certain level, another pancreatic hormone, **glucagon**, is called into play. Glucagon's effect is opposite that of insulin: it stimulates liver cells to break down glycogen and to carry out gluconeogenesis. Thus, under the influence of glucagon, the liver produces glucose and releases it into the blood.

The brain plays a major role in regulating food intake

Multiple brain areas and signals are involved in the regulation of food intake. Long ago it was discovered that damaging a region in the center of the rat hypothalamus resulted in the rats increasing their food intake and becoming obese. Damage to the lateral hypothalamus, however, led to decreased food intake and the rats became thin. In both cases the rats eventually reached a new equilibrium body weight; thus it appeared that a capacity for regulation remained, but the set point was altered.

We now know that another region of the hypothalamus, the **arcuate nucleus**, plays an important role in integrating a variety of feedback signals that influence food intake and body mass. Cells within the arcuate nucleus send axons to the ventromedial and dorsal hypothalamus, as well as to other brain areas that influence food intake and metabolism. One group of arcuate neurons projects to brain areas that inhibit food intake while the other projects to brain areas that stimulate food intake. But what stimulates or inhibits the activity of the arcuate neurons?

Several factors have been identified that reflect the body's energy balance. Three of these are the proteins insulin, leptin, and ghrelin. Insulin, as detailed earlier, is released when blood glucose levels are high. **Leptin** (Greek *leptos*, "thin") is released by fat cells in proportion to how much lipid they contain. Evidence that leptin is a satiety signal is described in **Figure 51.18**. **Ghrelin** is released by the stomach when it is empty; its levels rise before meals and fall after meals. In the arcuate

INVESTIGATINGLIFE

51.18 A Single-Gene Mutation Leads to Obesity in Mice

In mice the *Ob* gene codes for the protein leptin, a satiety factor that signals the brain when enough food has been consumed. The recessive *ob* allele is a loss-of-function allele, so *ob/ob* mice do not produce leptin; they do not experience satiety and become obese. The *D* gene encodes the leptin receptor, so mice homozygous for the recessive loss-of-function allele *db*, even if they produce leptin, cannot use it and so become obese.^a

HYPOTHESIS Mice who cannot produce the satiety signal protein leptin will not become obese if they are able to obtain leptin from an outside source.

Method

1. Create two strains of genetically obese laboratory mice, one of which lacks functional leptin (genotype *ob/ob*) and one which lacks the receptor for leptin (genotype *db/db*).
2. Create parabiotic pairs by surgically joining the circulatory systems of a non-obese (wild-type) mouse with a partner from one of the obese strains.
3. Allow mice to feed at will.

Parabiotic pair

Wild-type mouse (*Ob/ob*) Genetically obese mouse (either *ob/ob* or *db/db*)

Results

Parabiotic *ob/ob* mice obtain leptin from the wild-type partner and lose fat. Parabiotic *db/db* mice remain obese because they lack the leptin receptor and thus the leptin they obtain from their partner has no effect.

CONCLUSION The protein leptin is a satiety signal that acts to prevent overeating and resultant obesity.

Parabiotic Mice
Life10e.com/at51.3

nucleus, insulin and leptin activate the neurons that inhibit feeding and inhibit the neurons that stimulate feeding. Ghrelin has the opposite effect on these two groups of neurons.

WORKING WITH DATA:

Is Leptin a Satiety Signal?

Original Papers

Coleman, D. L., and K. P. Hummel. 1969. Effects of parabiosis of normal with genetically diabetic mice. *American Journal of Physiology* 217: 1298–1304.

Coleman, D. L. 1973. Effects of parabiosis of obese with diabetes and normal mice. *Diabetologia* 9: 294–297.

Analyze the Data

The study summarized in Figure 51.18 supported the hypothesis that there are two separate genes that signal the brain when enough food has been obtained—one that encodes a satiety signal and another that encodes a receptor protein for the signal. Subsequent studies revealed that the genes in question encode the hormone leptin and its receptor.

In addition to the experiment in Figure 51.18, the researchers purified leptin and injected it into wild-type mice (*Ob/Ob*) and into genetically obese mice that lacked the leptin gene (*ob/ob*). The data in the table below were collected before the injections began (baseline) and 10 days later.

- QUESTION 1**
Do the data support the hypothesis that leptin is a satiety signal? Explain your answer.
- QUESTION 2**
What factors might explain the loss of body mass in the leptin-injected *ob/ob* mice?

Parameter	Baseline		Day 10	
	<i>ob/ob</i>	<i>Ob/Ob</i>	<i>ob/ob</i>	<i>Ob/Ob</i>
Food intake (g/day)	12.0	5.5	5.0	6.0
Body mass (g)	64	35	50	38
Metabolic rate (ml O ₂ /kg/hr)	900	1,150	1,100	1,150
Body temperature (°C)	34.8	37.0	37.0	37.0

An integrative signal that could be playing a central role in regulation of feeding is the enzyme AMP-activated protein kinase (AMPK). When most cells are nutrient deprived, they produce AMPK, which stimulates the oxidation of substrates to replenish ATP. Fasting increases AMPK levels in the hypothalamus, and feeding reduces them. Insulin and leptin decrease AMPK activity in the hypothalamus, and ghrelin increases it. Thus AMPK could be a final common pathway for various signals controlling food intake.

RECAP 51.4

- The major controlling factors of gut function are an intrinsic nervous system and the hormones gastrin, secretin, and cholecystokinin. Insulin is the major hormonal controller of fuel metabolism. The hypothalamus controls food intake by generating sensations of hunger and satiety influenced by feedback from blood glucose and hormones, including insulin, leptin, and ghrelin.
- What are the roles of the three different classes of lipoproteins? **See p. 1066**
 - By what actions does insulin promote uptake and storage of energy during the absorptive state? **See pp. 1066–1067 and Figure 51.17**
 - What evidence supports the hypothesis that leptin influences satiety? **See pp. 1067–1068 and Figure 51.18**

Are there genes that predispose a person to obesity?

ANSWER

Many studies have demonstrated that a propensity for obesity is genetic and therefore heritable. About 30 studies comparing monozygotic and dizygotic twins led to the conclusion that the heritability of body mass is between 64 and 84 percent. Studies of monozygotic twins raised apart concluded that heritability of body mass was around 68 percent.

Single-gene causes of obesity have been observed but are rare. An example is a mutation of the leptin gene which has been found in a very small number of severely obese individuals, and these responded rapidly to leptin replacement therapy. To date the most commonly documented single-gene association with obesity is a mutation of the *MC4R* gene that encodes the melanocortin-4 receptor found on many hypothalamic neurons that inhibit feeding behavior. In a study population of Danish men, 2.5 percent of those who qualified as obese had mutations of the *MC4R* gene.

The Pima community of Arizona was among the first to be involved in a genome-wide survey. Many candidate genes were shown to be associated with obesity, but only weakly so. The conclusion must be that obesity is heritable, but except in a few very rare cases, it is a highly multigenic trait. Body mass is a function of Calories in minus Calories out, and genes influencing either side of this equation may be involved in obesity.

CHAPTERSUMMARY 51

51.1 What Do Animals Require from Food?

- Animals are **heterotrophs** that derive their energy and molecular building blocks, directly or indirectly, from **autotrophs**.
- Carbohydrates, fats, and proteins in food supply animals with energy. A measure of the energy content of food is the **kilocalorie (kcal)**. Excess caloric intake is stored as glycogen and fat. **Review Figure 51.2**
- For many animals, food provides essential **carbon skeletons** that they cannot synthesize themselves. **Review Figure 51.4**
- Most researchers consider 8 amino acids to be essential for adult humans; some believe that infants require as many as 12 **essential amino acids** in their diet. **Macronutrients** are mineral elements needed in large quantities; **micronutrients** are needed in small amounts. **Review Figure 51.5, Table 51.1, ACTIVITY 51.1**
- **Vitamins** are organic molecules that must be obtained in food. **Review Table 51.2, ACTIVITY 51.2**
- **Malnutrition** results when any essential nutrient is lacking from the diet. Chronic malnutrition causes **deficiency disease**.

51.2 How Do Animals Ingest and Digest Food?

- Animals can be characterized by how they acquire nutrients: **saprobies** and **detritivores**, or **decomposers**, depend on dead organic matter, **filter feeders** strain the aquatic environment for small food items, **herbivores** eat plants, and **carnivores** eat other animals. Behavioral and anatomical adaptations reflect these feeding strategies. **See ACTIVITY 51.3**
- Digestion involves the breakdown of complex food molecules into monomers that can be absorbed and used by cells. In most animals, digestion takes place in a tubular gut. **Review Figure 51.7**
- Absorptive areas of the vertebrate gut are characterized by a large surface area produced by extensive folding and numerous **villi** and **microvilli**. **Review Figure 51.8**
- Hydrolytic enzymes break down proteins, carbohydrates, and fats into their monomeric units.

51.3 How Does the Vertebrate Gastrointestinal System Function?

- The vertebrate gut can be divided into several compartments with different functions. **Review Figure 51.9, ACTIVITY 51.4**
- The cells and tissues of the vertebrate gut are organized in the same way throughout its length. The innermost tissue layer, the **mucosa**, is the secretory and absorptive surface. The **submucosa** contains blood and lymph vessels and a nerve network that is sensory and also controls gut secretions. External to the submucosa are two smooth muscle layers. Between the two muscle layers is another nerve network that controls the movements of the gut. **Review Figure 51.10**
- Swallowing is a reflex that pushes a bolus of food into the **esophagus**. **Peristalsis** and **segmentation movements** of the gut move the bolus down the esophagus and through the entire length of the gut. **Sphincters** block the gut at certain locations, but they relax as a wave of peristalsis approaches. **Review Figure 51.11**
- Digestion begins in the **mouth**, where amylase is secreted with the saliva. Digestion of protein begins in the **stomach**, where parietal cells secrete HCl and chief cells secrete pepsinogen, a zymogen that becomes pepsin when activated by low pH and

autocatalysis. The mucosa also secretes mucus, which protects the tissues of the gut. **Review Figure 51.12**

- In the **duodenum**, pancreatic enzymes carry out most of the digestion of food. **Bile** from the liver and **gallbladder** emulsifies fats into **micelles**. Bicarbonate ions from the **pancreas** neutralize the pH of the **chyme** entering from the stomach to produce an environment conducive to the actions of pancreatic enzymes such as **trypsin**. **Review Figure 51.13, Table 51.3**
- Final enzymatic cleavage of polypeptides and disaccharides occurs among the microvilli of the intestinal mucosa. Amino acids, monosaccharides, and inorganic ions are absorbed by the microvilli. Specific transporter proteins are sometimes involved. Symporters often power the absorption of nutrients.
- Fats broken down by **lipases** are absorbed mostly as monoglycerides and fatty acids and are resynthesized into triglycerides within the gut epithelium. The triglycerides are combined with cholesterol and phospholipids and coated with protein to form **chylomicrons**, which pass out of the mucosal cells and into lymphatic vessels in the submucosa. **Review Figure 51.14, ANIMATED TUTORIAL 51.1**
- Water and ions are absorbed in the large intestine as waste matter and consolidated into **feces**, which are periodically eliminated.
- Microorganisms in some compartments of the gut digest materials that their host cannot. **Review Figure 51.15**

51.4 How Is the Flow of Nutrients Controlled and Regulated?

- Autonomic reflexes coordinate activity of the digestive tract, which has an intrinsic nervous system that can act independently of the CNS.
- The actions of the stomach and small intestine are largely controlled by the hormones **gastrin**, **secretin**, and **cholecystokinin**. **Review Figure 51.16**
- The liver plays a central role in directing the traffic of fuel molecules. In the **absorptive state**, the liver takes up and stores fats and carbohydrates, converting monosaccharides to glycogen or fats. The liver also takes up amino acids and uses them to produce blood plasma proteins, and can engage in gluconeogenesis.
- Fat and cholesterol are shipped out of the liver as **low-density lipoproteins**. **High-density lipoproteins** act as acceptors of cholesterol and bring fat and cholesterol back to the liver.
- **Insulin** largely controls fuel metabolism during the absorptive state and promotes glucose uptake as well as glycogen and fat synthesis. In the **postabsorptive state**, lack of insulin blocks the uptake and use of glucose by most cells of the body except neurons. If blood glucose levels fall, **glucagon** secretion increases, stimulating the liver to break down glycogen and release glucose to the blood. **Review Figure 51.17, ANIMATED TUTORIAL 51.2**
- Food intake is governed by sensations of hunger and satiety, which are determined by brain mechanisms responding to feedback signals such as insulin, **leptin**, and **ghrelin**. **Review Figure 51.18, ANIMATED TUTORIAL 51.3**

CHAPTER REVIEW

REMEMBERING

- Which statement about essential amino acids is true?
 - They are not found in vegetarian diets.
 - They are stored by the body until they are needed.
 - Without them, the body is undernourished.
 - All animals require the same ones.
 - Humans can acquire all of theirs by eating milk, eggs, and meat.
- The digestive enzymes of the small intestine
 - do not function well at a low pH.
 - are produced and released in response to circulating secretin.
 - are produced and released under neural control.
 - are all secreted by the pancreas.
 - are all activated by an acidic environment.
- Which statement about nutrient absorption by the intestinal mucosal cells is true?
 - Carbohydrates are absorbed as disaccharides.
 - Fats are absorbed as fatty acids and monoglycerides.
 - Amino acids move across the plasma membrane only by diffusion.
 - Bile transports fats across the plasma membrane.
 - Most nutrients are absorbed in the duodenum.
- Chylomicrons are like the tiny micelles of dietary fat in the lumen of the small intestine in that both
 - are coated with bile.
 - are lipid-soluble.
 - travel through the lymphatic system.
 - contain triglycerides.
 - are coated with lipoproteins
- Which of the following is stimulated by cholecystokinin?
 - Stomach motility
 - Release of bile
 - Secretion of hydrochloric acid
 - Secretion of bicarbonate ions
 - Secretion of mucus

UNDERSTANDING & APPLYING

- Several popular diet books recommend high fat and protein intake and low carbohydrate intake as a means of losing body mass. What is the rationale for a high-fat and high-protein diet?
- Explain how insulin is involved in at least five differences between the management of fuel molecules in the absorptive and the postabsorptive state.
- Trace the history of a fatty acid molecule from a slice of cheese pizza to a plaque on a coronary artery. Into what possible forms and structures might it have been converted as it passed through the body? Describe a direct and an indirect route it could have taken.

EVALUATING & ANALYZING

- The pancreatic duct cells and the parietal cells of the stomach both express high levels of carbonic anhydrase. Explain how the actions of this enzyme are similar in both cases, but how the consequences in terms of influences on the pH of the blood are different.
- Body mass is a function of Calories in minus Calories out. If genome scans of obese individuals show that most of the associated genes play roles in the hypothalamic regulatory pathways, what does that tell us about which side of the energy balance equation is the most important in contributing to obesity?

Salt and Water Balance and Nitrogen Excretion

CHAPTER OUTLINE

- 52.1** How Do Excretory Systems Maintain Homeostasis?
- 52.2** How Do Animals Excrete Nitrogen?
- 52.3** How Do Invertebrate Excretory Systems Work?
- 52.4** How Do Vertebrates Maintain Salt and Water Balance?
- 52.5** How Does the Mammalian Kidney Produce Concentrated Urine?
- 52.6** How Are Kidney Functions Regulated?

BLOOD, SWEAT, AND TEARS taste salty because they have the ionic composition of the extracellular fluid that bathes the cells of the body. The volume and composition of the extracellular fluid must be regulated and kept relatively free of wastes. Maintaining homeostasis of the extracellular fluid is the job of the excretory system. It is a challenging job that sometimes requires getting rid of excess fluids and conserving ions, and at other times requires conserving fluids and excreting excess ions.

The nature of the challenge depends on an animal's environment and lifestyle. Some desert animals rarely if ever encounter open water, so drinking is not an option. Animals that live in fresh water have the opposite challenge: water continuously enters their bodies by osmosis and in their food. Animals that live in salt water face a challenge similar to that of the desert dwellers—they need to conserve water and excrete ions. The physiological mechanisms all animals have to maintain salt and water balance are similar, but they are used in different ways to solve the unique problems of each species. Consider, for example, vampire bats.

Vampire bats feed on the blood of animals such as goats and cattle, using sharp incisor teeth to make a small incision (usually on the legs and ankles of a sleeping victim) and then lapping up the blood. The bat's saliva has an anticoagulant that keeps the blood flowing. Blood contains nutritious protein, but it consists mostly of water. Blood meals may be few and far between, so

Blood as Fast Food The vampire bat *Desmodus rotundus* is able to adjust its excretory physiology rapidly from water-excreting to water-conserving, depending on whether it is ingesting or digesting its blood meal.

the bat quickly consumes as much as it can—up to half its body mass. To maximize its protein intake and keep its weight low enough to fly, it rapidly eliminates the water from its meal. Within minutes of starting to feed, the bat is producing copious dilute urine.

Once feeding ends, this high rate of water loss must stop—now the bat is metabolizing protein and must excrete large amounts of nitrogenous wastes while conserving water. Within minutes, the bat's excretory system switches from producing abundant, dilute urine to producing a tiny amount of highly concentrated urine. To conserve water, vampire bats (and some desert rodents) can produce urine that is 15 times more concentrated than their own blood. In one feeding cycle, the vampire bat rapidly transitions from an excretory physiology typical of a mammal living in an environment with abundant fresh water to that of a desert mammal that never sees water.

How do desert rodents and vampire bats make highly concentrated urine?

See answer on p. 1090.

52.1 How Do Excretory Systems Maintain Homeostasis?

Homeostasis of the extracellular fluid (the blood plasma and interstitial fluid; see Section 40.1) is critical for several reasons:

- The solute concentration of the extracellular fluid determines the water balance of the cells of the body.
- The specific ionic composition of the extracellular fluid influences many functions of various types of cells. Consider, for example, the importance of ion concentration gradients between the extracellular fluid and the cytoplasm of nerve and muscle cells (see Sections 45.2 and 48.1).
- The health of cells requires the elimination of nitrogenous wastes.

The problems that have to be solved to maintain homeostasis of the extracellular fluid depend on the environment in which a species lives (salt water, fresh water, or terrestrial) and its life-style, as we saw in the case of the vampire bat in the opening story. Animals depend on **excretory systems** to maintain the volume, concentration, and composition of their extracellular fluids, and to excrete wastes.

Water enters or leaves cells by osmosis

The volume of cells depends on whether they take up water from or lose water to the extracellular fluid. The movement of water across cell plasma membranes depends on differences in solute concentration on the two sides of the membrane and on the permeability of the membrane. This is the process of osmosis, which we discussed in Sections 6.3 and 35.1. If the solute concentration of the extracellular fluid is less than that of the cytoplasm, water moves into the cells, causing them to swell and possibly burst (see Figure 6.9). If the solute concentration of the extracellular fluid is greater than that of the cytoplasm, the cells lose water and shrink. Thus the solute concentration of the extracellular fluid affects both the volume and the solute concentration of the cells.

Animal physiologists use the term **osmolarity** in discussing osmosis. The osmolarity of a solution is the number of moles of osmotically active solutes per liter of solvent. Thus a 1 molar solution of glucose is also a 1 osmolar (1 osmole per liter) solution, but a 1 molar solution of sodium chloride (NaCl) is a 2 osmolar solution, because each NaCl molecule dissociates into two osmotically active ions.

Excretory systems control extracellular fluid osmolarity and composition

Excretory systems control the osmolarity and composition of the extracellular fluids by excreting solutes that are present in excess (such as NaCl when we eat lots of salty food) and conserving solutes that are valuable or in short supply (such as glucose and amino acids). Excretory systems also eliminate the toxic waste products of protein metabolism. The output of the excretory system is called **urine**.

Three basic processes are common to a wide variety of animal excretory systems: filtration, secretion, and reabsorption. Filtered extracellular fluid contains no cells or large

molecules, such as proteins. In animals with closed circulatory systems, the blood plasma is usually filtered from capillaries into associated tubules. The walls of the capillaries and of the tubules are the filter, and the filtration is driven by blood pressure. As the filtrate flows through the tubules, its composition and concentration are modified through processes of secretion and reabsorption to form the urine that leaves the body.

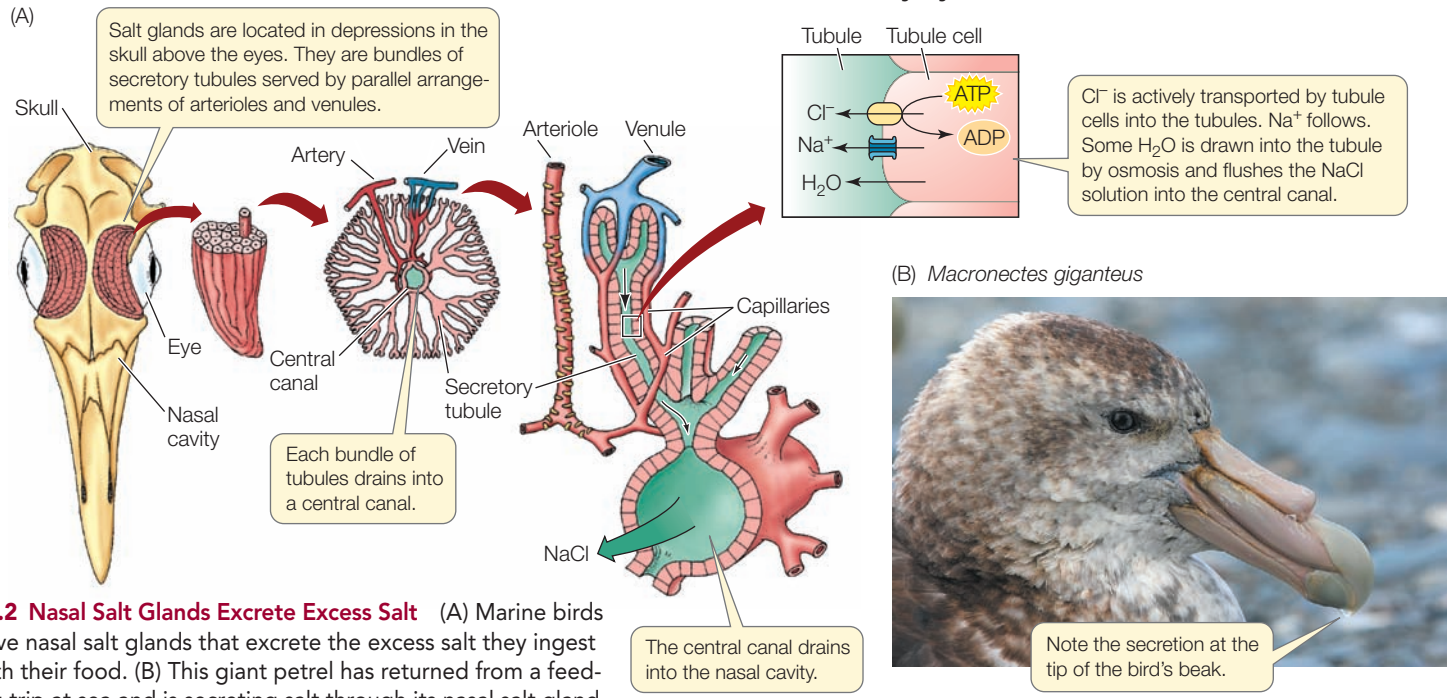

In all of the discussions that follow about the movement of water across membranes, it is important to remember that there are no mechanisms for the active transport of water. The movement of water is due either to a pressure difference (filtration) or to a difference in solute concentration (osmosis). Water always flows down a pressure gradient or up a solute concentration gradient.

Aquatic invertebrates can conform to or regulate their osmotic and ionic environments

Most invertebrates that live in seawater conform to the osmotic concentration of their environment over a fairly wide range of salinities and are therefore called **osmoconformers** (Figure 52.1). The osmolarity of seawater in the open ocean is about 1,000 milliosmoles/liter (mosm/l), but it can vary quite a bit in estuaries where it is diluted by an influx of fresh water or in evaporating tide pools as the salt gets concentrated. Osmoconformity can result in considerable energetic savings, as it costs metabolic energy to move ions across membranes to achieve

52.1 Some Marine Invertebrates Osmoregulate Some aquatic animals, such as mussels, experience an extreme range of salt concentrations in their environment and are osmoconformers over much of that range. Other aquatic animals, such as brine shrimp, are osmoregulators in that they maintain a relatively constant osmolarity of their extracellular fluids as environmental salinity varies.

52.2 Nasal Salt Glands Excrete Excess Salt (A) Marine birds have nasal salt glands that excrete the excess salt they ingest with their food. (B) This giant petrel has returned from a feeding trip at sea and is secreting salt through its nasal salt gland.

osmotic regulation. However, osmoconformity is not an option for freshwater animals. No cell can do without ions or nutrients, so freshwater animals always have to expend energy to conserve salts and excrete water.

Some marine invertebrates maintain a rather constant osmolarity of their extracellular fluids as the osmolarity of the environment changes, and these animals are therefore called **osmoregulators** (see Figure 52.1). Osmoregulators in the marine environment mostly maintain their osmotic concentration considerably below that of the environment and are therefore engaged in **hypoosmotic regulation**. Occasionally, however, seawater is diluted by an influx of fresh water, as in estuaries, and animals must maintain their osmotic concentrations above that of the environment—a process called **hyperosmotic regulation**.

The brine shrimp *Artemia* illustrated in Figure 52.1 is an osmoregulator with an enormous range of tolerances. *Artemia* are found in huge numbers in the most salty environments known, such as Utah's Great Salt Lake and in coastal evaporation ponds where salt is concentrated for commercial purposes (see Figure 26.17) and can reach an osmolarity of 2,500 mosm/l. No animal could survive with internal osmolarities that high; such a solute concentration would cause proteins to denature. *Artemia* are able to exploit these environments because of their ability to regulate hypoosmotically by actively transporting NaCl from their extracellular fluid out across their gill membranes to the environment. *Artemia* cannot survive in fresh water, but they can live in dilute seawater by reversing the direction of transport of NaCl across their gill membranes to maintain the osmolarity of their extracellular fluids above that of the environment, thus becoming hyperosmotic regulators.

Virtually all marine invertebrates are ionic conformers with respect to certain ions such as Na^+ and Cl^- in their extracellular fluids—that is, the extracellular concentrations of these ions are the same as in seawater. Thus these animals avoid the considerable metabolic costs of moving ions across membranes to maintain concentration differences between their

extracellular fluids and the seawater. However, most marine animals (with the exception of echinoderms) are ionic regulators with respect to certain ions; they employ active transport mechanisms to maintain these ions in their extracellular fluid at optimal concentrations.

Vertebrates are osmoregulators and ionic regulators

All aquatic vertebrates, with two exceptions, regulate the osmolarity of their extracellular fluids at 300 mosm/l. In doing so, they are selective in which ions they conserve and which ions they excrete; thus they are ionic regulators as well as osmoregulators. One exception is the hagfish, a primitive jawless fish and a very ancient vertebrate group (see Figure 33.10). Hagfish are osmoconformers as well as ionic conformers for many of the ions found in seawater. The other exception is the chondrichthyans (cartilaginous fishes, the sharks and rays). Chondrichthyans retain in their extracellular fluid two organic solutes, urea and trimethylamine oxide (TMAO), that are products of protein metabolism. As a result, their extracellular fluid is slightly hyperosmotic to the seawater and they gain water by osmosis.

Terrestrial vertebrates obtain their salts mostly from food and regulate the ionic composition of their extracellular fluids by conserving some ions and excreting others. For example, herbivores have to conserve Na^+ because the plants they eat have low concentrations of Na^+ . By contrast, birds that feed on marine animals must excrete the excess sodium they ingest with their food. Such birds, which include penguins and gulls, excrete excess salt through their nasal salt glands. These glands use active transport of Cl^- ions (with Na^+ and some water following passively) into a series of canals and ducts to produce a concentrated solution of NaCl that empties into the nasal cavity (Figure 52.2). These birds can be seen frequently sneezing or shaking their heads to get rid of the salty droplets excreted from their nasal salt glands.

RECAP 52.1

Excretory systems control water and salt balance and the excretion of nitrogenous waste products through three mechanisms: filtration of body fluids to form urine, active secretion of substances into the urine, and active reabsorption of substances from the urine.

- Describe the two mechanisms used to move water across membranes. **See p. 1072**
- What different salt and water balance problems might animals encounter in marine, freshwater, and terrestrial environments? What are some of the ways they meet those challenges? **See pp. 1072–1073 and Figures 52.1 and 52.2**

In addition to maintaining salt and water balance, animals must eliminate the waste products of metabolism from their extracellular fluids. The major problem is nitrogen. When nitrogen-containing molecules are broken down by metabolism, the end product can be toxic.

52.2 How Do Animals Excrete Nitrogen?

The end products of the metabolism of carbohydrates and fats are water and carbon dioxide, which are not difficult to eliminate. Proteins and nucleic acids, however, contain nitrogen, so their metabolism produces nitrogenous wastes in addition to water and carbon dioxide.

Animals excrete nitrogen in a number of forms

The most common nitrogenous waste is **ammonia** (NH_3). Because it is highly toxic, ammonia is either excreted continuously to prevent its accumulation or is detoxified by conversion into **urea** or **uric acid** (Figure 52.3).

AMMONIA Ammonia is highly soluble in water and diffuses rapidly, so its continuous excretion is relatively simple for many aquatic animals that continuously lose ammonia from their blood to the environment by diffusion across their gill

membranes. Animals that excrete ammonia, such as aquatic invertebrates and bony fishes, are **ammonotelic**.

If ammonia builds up in the extracellular fluids, it becomes toxic at rather low levels and is a dangerous metabolite for terrestrial animals and for those aquatic animals that cannot continuously excrete ammonia. These animals must convert ammonia into urea or uric acid.

UREA **Ureotelic** animals, such as mammals, amphibians, chondrichthans (sharks and rays), and hagfish excrete urea as their principal nitrogenous waste product. Urea is quite soluble in water, but its excretion can result in a large loss of water that many animals can ill afford. As we will see later in this chapter, mammals have evolved excretory systems that conserve water by producing urine that has a high concentration of urea. As we mentioned in Section 52.1, sharks, rays, and hagfish retain high concentrations of urea and TMAO in their extracellular fluid, so that it is hyperosmotic to seawater.

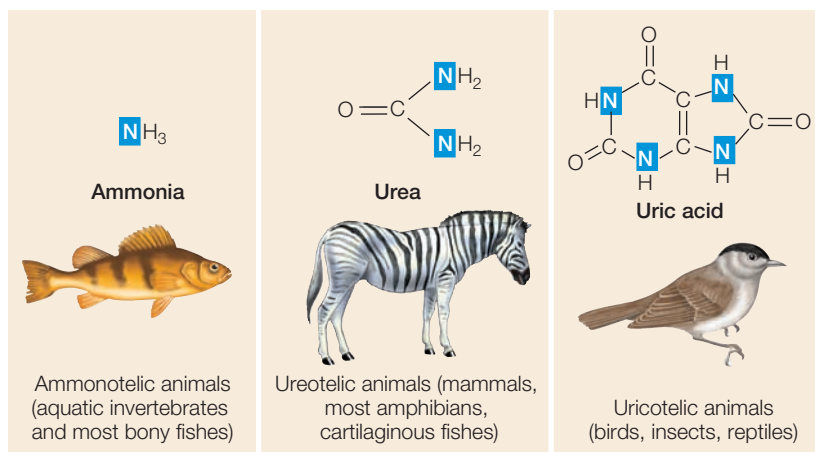

URIC ACID Animals that conserve water by excreting nitrogenous wastes mostly as uric acid are **uricotelic**. Insects, reptiles (including birds), and some amphibians are uricotelic. Uric acid is not very soluble in water, so it forms a colloidal suspension in the urine and is excreted as a semisolid (for example, the whitish material in bird droppings). A uricotelic animal loses very little water as it disposes of its nitrogenous wastes.

Most species produce more than one nitrogenous waste

Humans are ureotelic, but we also excrete uric acid. The uric acid in human urine comes largely from the metabolism of nucleic acids and caffeine. If uric acid levels in the extracellular fluid rise too high, uric acid crystals can precipitate in joints and cause the age-old malady called gout. Because solubility goes down with temperature, uric acid crystals usually precipitate first in the extremities, especially the big toe. Pain in the big toe is a telltale symptom of gout.

Humans can also excrete ammonia, which is an important mechanism for regulating the pH of the extracellular fluids. As

52.3 Waste Products of Metabolism The metabolism of proteins and nucleic acids produces nitrogenous wastes. Many aquatic animals, including most fishes, excrete nitrogenous wastes as ammonia, which is highly diffusible and soluble in an aqueous environment. Most terrestrial animals and some aquatic animals excrete either urea or uric acid. Urea is more soluble in water and is the major nitrogenous excretory product for mammals, amphibians, and some fishes. Uric acid is not very soluble in water and is the major nitrogenous excretory product for reptiles, birds, insects, and some amphibians.

we will see later in this chapter, excreted ammonia buffers the urine and enables the excretion of excess hydrogen ions.

Species that live in different habitats at different developmental stages may use more than one mechanism of nitrogen excretion. The tadpoles of frogs and toads, for example, excrete ammonia across their gill membranes, but adult frogs and toads generally excrete urea. Some adult amphibians that live in arid habitats excrete uric acid.

RECAP 52.2

Ammonia is a common metabolic waste product of nitrogen-containing molecules. Most aquatic animals excrete ammonia by diffusion into the water. Terrestrial animals and some aquatic animals detoxify ammonia by conversion to urea or uric acid.

- Explain the significance of high concentrations of urea in the blood of sharks. **See p. 1074**
- Why might you expect a species from an arid habitat to use uric acid as its primary nitrogenous waste product? **See p. 1074 and Figure 52.3**

Animals exhibit a variety of adaptations for dealing with the challenges of salt and water balance in different environments. All of these adaptations, however, are based on two basic mechanisms—namely, filtration and tubular processing of the filtrate to conserve some solutes and excrete others.

52.3 How Do Invertebrate Excretory Systems Work?

Freshwater and terrestrial invertebrates have a wide variety of adaptations for maintaining salt and water balance and excreting nitrogen. In this section we will explore three examples of invertebrate excretory systems: protonephridia, metanephridia, and Malpighian tubules. Each of these systems produces an extract of interstitial fluid lacking large molecules. They then change the solute composition (ions and small molecules) of that fluid to form an excretory product.

The protonephridia of flatworms excrete water and conserve salts

Many free-living flatworms, such as *Planaria*, live in fresh water. These animals excrete water through an elaborate network of tubules running throughout their bodies. The tubules end in flame cells, so called because each cell has a tuft of cilia projecting into the tubule (**Figure 52.4**). The beating of the cilia gives the appearance of a flickering flame. A flame cell and a tubule together form a **protonephridium** (plural *protonephridia*; Greek *proto*, “before”; *nephros*, “kidney”).

Extracellular fluid enters the tubules by filtration. The beating of the cilia causes a slight negative pressure in the tubule, and movements of the animal create positive pressure in the extracellular fluid. This pressure difference causes extracellular fluid to be filtered through tiny spaces between tubule cells. The filtrate flows toward the animal’s excretory pore, and along the way the cells of the tubules modify the composition

52.4 Protonephridia in Flatworms The protonephridia of the flatworm *Planaria* consist of tubules ending in flame cells. In the region of the flame cells, body fluid is filtered between the tubule cells. The composition of the filtrate is modified as it flows down the tubule.

of the fluid by reabsorption and secretion of specific ions and molecules. Because more ions are reabsorbed than are secreted, the urine that leaves the flatworm’s body is less concentrated than the extracellular fluid. Thus the protonephridium conserves ions and excretes water and wastes.

The metanephridia of annelids process coelomic fluid

Filtration of body fluids and modification of urine by tubules are highly developed processes in annelid worms such as the earthworm. Annelids are segmented, and in each segment they have a fluid-filled body cavity called a coelom (see Figure 32.11). Annelids have a closed circulatory system through which blood is pumped under pressure. The pressure causes the blood to be filtered across the thin, permeable capillary walls into the coelom. Some waste products, such as ammonia, diffuse directly from the tissues into the coelom. Where does this coelomic fluid go?

Each segment of the earthworm contains a pair of **metanephridia** (singular *metanephridium*; Greek *meta*, “akin to”). Each metanephridium begins as a ciliated, funnel-like opening called a nephrostome. The nephrostome resides in one segment and continues as a tubule in the next segment. The tubule ends in a pore, called a nephridiopore, that opens to the outside of the animal (**Figure 52.5**). Coelomic fluid is swept into the metanephridia through the ciliated nephrostomes. As the fluid passes through the tubules, their cells actively reabsorb certain molecules from it and actively secrete other molecules into it. What leaves the animal through the nephridiopores is a dilute urine containing nitrogenous wastes and other solutes.

52.5 Metanephridia in Earthworms The metanephridia of annelids are arranged segmentally. The cross section at the left end shows a pair of metanephridia. Three longitudinal sections (right) show only one metanephridium of the two in each segment. Coelomic fluid enters the nephrostome and flows through tubules leading to the nephridiopore. A close association of the tubules and blood capillaries facilitates the active exchange of substances between the blood and the tubular fluid.

Go to Activity 52.1 Annelid Metanephridia
Life10e.com/ac52.1

Malpighian tubules of insects use active transport to excrete wastes

Insects can excrete nitrogenous wastes with very little loss of water and can therefore live in the driest habitats on Earth. The insect excretory system consists of **Malpighian tubules**. An individual insect has from 2 to more than 100 of these blind-ended tubules that open into the gut between the midgut and hindgut (Figure 52.6).

Insects have an open circulatory system and therefore cannot use a pressure difference to filter extracellular fluids into the Malpighian tubules. Instead, the cells of the tubules actively transport uric acid, potassium ions, and sodium ions from the extracellular fluid into the tubules. The high concentration of

solutes in the tubules causes water to follow osmotically, which flushes the tubule contents toward the gut.

The epithelial cells of the hindgut and rectum actively transport sodium and potassium ions from the gut contents back into the extracellular fluid. This local transport of salts

52.6 Malpighian Tubules in Insects The blind, thin-walled Malpighian tubules are attached to the junction of the insect's midgut and hindgut and project into the spaces containing extracellular fluid. This system makes it possible to excrete wastes with very little loss of water.

creates an osmotic gradient that pulls water out of the rectal contents. As its concentration increases, the uric acid forms a colloidal suspension, freeing even more water to be reabsorbed. Remaining in the rectum is the uric acid mixed with other wastes; this semisolid matter is what the insect excretes. If you ever park your car under a tree being visited by bees, you will find the little excretory droplets from the bees all over the car. The Malpighian tubule system is a highly effective mechanism for excreting nitrogenous wastes and some salts without giving up much water.

RECAP 52.3

Protonephridia and metanephridia work by creating a filtrate of the body fluids that is modified by the secretion and reabsorption of specific substances before being excreted. Insect Malpighian tubules actively secrete uric acid and other solutes into closed tubules.

- Describe how an earthworm filters its blood and produces urine. [See p. 1075 and Figure 52.5](#)
- How do Malpighian tubules make it possible for some insect species to survive where there is no free water? [See pp. 1076–1077 and Figure 52.6](#)

Having described how several invertebrate groups handle nitrogen excretion, we will next consider the nephron—the basic unit of the vertebrate excretory system—and how it evolved to be able to respond to a variety of salt and water balance challenges and maintain a relatively constant internal environment.

52.4 How Do Vertebrates Maintain Salt and Water Balance?

The main excretory organ of vertebrates is the **kidney**, and the functional unit of the kidney is the **nephron**, which has a blood vessel component and a tubule component. The vascular component begins with a knot of capillaries that are highly permeable and filter the blood into the tubule component. The blood vessels also carry substances to the tubules for secretion and carry away substances that the tubule cells reabsorb. Nephrons can filter large volumes of blood and achieve bulk reabsorption of salts and other valuable molecules such as glucose, making the vertebrate kidney well adapted for the excretion of excess water.

The evolution of vertebrates is thought to have begun with a marine predecessor that moved into a freshwater habitat. The excretory system of this vertebrate ancestor would have evolved to excrete large quantities of water, enabling the osmoregulatory capacities seen in present-day vertebrates. But if the early vertebrates evolved to excrete water, how did subsequent vertebrate lineages adapt to environments where water must be conserved and salts excreted? The answer to this question differs among vertebrate groups. Even among the marine fishes, the excretory adaptations of the bony fishes differ from those of the chondrichthyans. Reptiles, birds, and mammals have excretory systems that conserve water. Reptiles and birds achieve this mainly by being uricotelic and

producing a semisolid excretory product that contains little water. Mammals, in contrast, are ammonotelic; they excrete a liquid waste product but have evolved the ability to produce a highly concentrated urine.

Marine fishes must conserve water

Marine bony fishes osmoregulate their extracellular fluids to maintain them at one-third to one-half the osmolarity of seawater. Their only source of water is the sea around them, so they must conserve water and excrete excess solutes. Marine bony fishes cannot produce urine that is more concentrated than their extracellular fluids, so they minimize water loss by producing very little urine. In contrast, freshwater fishes produce lots of dilute urine.

If marine bony fishes cannot excrete excess solutes in their urine, how do they deal with the large salt loads they ingest with food? Marine bony fishes do not absorb from their guts some of the ions they take in, especially divalent ions such as Mg^{2+} or SO_4^{2-} . NaCl , the major salt ingested, is actively excreted across the gill membranes. As we mentioned earlier, bony fishes can lose their nitrogenous waste, ammonia, by diffusion across their gill membranes.

Chondrichthyans (sharks and rays) are osmoconformers but not ionic conformers. As we have discussed, they raise the osmolarity of their body fluids in a unique way. Unlike bony fishes, they retain urea and trimethylamine oxide in their extracellular fluids so that it is hyperosmotic to seawater. These species have adapted to a concentration of urea in the body fluids that would be toxic to other vertebrates. Sharks and rays still have the problem of excreting the large amounts of salts they take in with their food. They solve this problem by having a gland in the rectum that actively secretes NaCl by a mechanism similar to that of the nasal salt glands of seabirds.

Terrestrial amphibians and reptiles must avoid desiccation

Most amphibians live in or near fresh water, and they stay in humid habitats when they do venture from the water. Like freshwater fishes, most amphibians produce large amounts of dilute urine and conserve salts. Some amphibians, however, have adapted to habitats that require water conservation.

Amphibians living in dry terrestrial environments have skin with a reduced permeability to water. Some secrete a waxy substance over the skin to waterproof it. Several species of frogs that live in arid regions of Australia burrow deep into the ground and remain there during long dry periods. They enter **estivation**, a state of very low metabolic activity and therefore low water turnover. When it rains, the frogs come out of estivation, feed, and reproduce. Their most interesting adaptation is an enormous urinary bladder. Before entering estivation, they fill the bladder with dilute urine, which can amount to one-third of their body weight. This dilute urine serves as a water reservoir that is gradually reabsorbed into the blood during the long period of estivation. Aboriginal peoples have learned to locate these buried frogs and use them as an emergency source of water.

Reptiles occupy habitats ranging from aquatic to extremely hot and dry. In fact, snakes, lizards, and birds are among the most prominent members of many desert faunas. Three major adaptations have freed reptiles from the close association with water that is necessary for most amphibians (see Section 33.4):

- Reptiles are amniotes that do not need fresh water to reproduce because they employ internal fertilization and lay eggs with shells that retard evaporative water loss.
- Reptiles have a dry epidermis (skin) that retards evaporative water loss.
- Reptiles excrete nitrogenous wastes as uric acid semisolids, losing little water in the process.

Mammals can produce highly concentrated urine

Mammals occupy diverse habitats, many of which present special excretory system challenges. The most challenging environments are those in which water is severely limited. Mammals have a variety of adaptations to conserve water, but chief among them is the ability to produce urine that is more concentrated than their extracellular fluids. They are able to concentrate their urine because of adaptations of their kidneys that we will explore in detail in Section 52.5. To understand how these adaptations work, however, we must first describe the structure and function of the vertebrate nephron.

The nephron is the functional unit of the vertebrate kidney

Urine formation in vertebrate nephrons involves three main processes (Figure 52.7):

- **Filtration.** Each nephron has a dense bed of capillaries called a **glomerulus** (plural *glomeruli*). The glomerulus is highly permeable to water, ions, and small molecules but impermeable to large molecules. Blood pressure drives the movement of water and small-molecular-weight solutes out of the glomerular capillaries.
- **Tubular reabsorption.** The filtrate from the glomerulus flows into the **renal tubule**. Cells in the renal tubule modify the filtrate by reabsorbing specific ions, nutrients, and water, returning these to the blood, and leaving behind and concentrating excess ions and waste products such as urea.
- **Tubular secretion.** The filtrate in the renal tubule is further modified by tubule cells transporting substances into the tubule. These are substances that the body needs to excrete.

Blood enters the glomerular capillaries via an **afferent arteriole** and leaves the glomerulus in an **efferent arteriole**. This short vessel is called an arteriole because it feeds another capillary bed, called the **peritubular capillaries**, that intimately surrounds the renal tubules. Peritubular capillaries deliver substances to the renal tubule cells that these cells secrete into the

52.7 The Vertebrate Nephron The vertebrate nephron consists of a renal tubule closely associated with two capillary beds, the glomerulus and the peritubular capillaries.

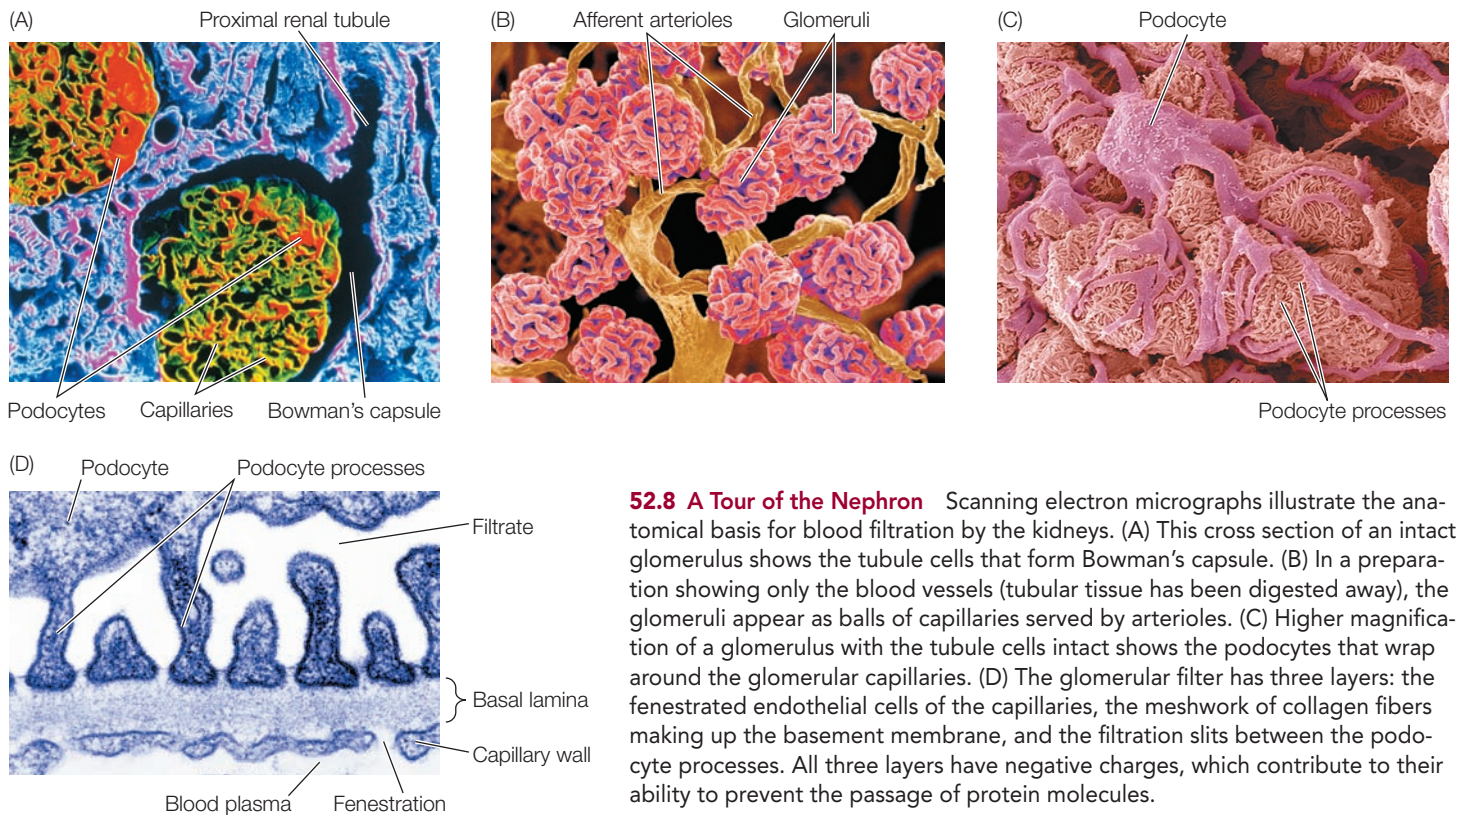

Go to Activity 52.2 The Vertebrate Nephron
Life10e.com/ac52.2

urine. The peritubular capillaries also carry away substances that the tubule cells reabsorb from the urine.

Blood is filtered into Bowman's capsule

The renal tubule begins with **Bowman's capsule** (see Figure 52.7), which encloses the glomerulus (Figure 52.8A and B). The glomerulus appears to be pushed into Bowman's capsule much like a fist pushed into an inflated balloon. The cells of the capsule that are in direct contact with the glomerular capillaries are called **podocytes** (Figure 52.8C). These highly specialized cells have numerous armlike extensions, each with hundreds of fine, fingerlike processes. The podocytes wrap around the capillaries so that their processes interdigitate and intimately cover the capillaries.

The glomerulus filters the blood to produce a fluid (the renal filtrate) that lacks cells and large molecules. The walls of the capillaries, the basal lamina of the capillary endothelium, and the

52.8 A Tour of the Nephron Scanning electron micrographs illustrate the anatomical basis for blood filtration by the kidneys. (A) This cross section of an intact glomerulus shows the tubule cells that form Bowman's capsule. (B) In a preparation showing only the blood vessels (tubular tissue has been digested away), the glomeruli appear as balls of capillaries served by arterioles. (C) Higher magnification of a glomerulus with the tubule cells intact shows the podocytes that wrap around the glomerular capillaries. (D) The glomerular filter has three layers: the fenestrated endothelial cells of the capillaries, the meshwork of collagen fibers making up the basement membrane, and the filtration slits between the podocyte processes. All three layers have negative charges, which contribute to their ability to prevent the passage of protein molecules.

podocytes of Bowman's capsule all participate in filtration. Fenestrations in the walls of the capillaries (see Section 50.4) allow water and many solute molecules, but not red blood cells, to pass through. The meshwork of the basal lamina and the spaces between the processes of the podocytes are even finer and prevent large molecules from leaving the capillaries (**Figure 52.8D**). The arterial pressure of the blood entering the permeable capillaries causes the filtration of water and small molecules out of the glomerular capillaries and into the Bowman's capsule. The glomerular filtration rate is high because blood pressure in the glomerular capillaries is unusually high, and because the capillaries of the glomerulus, along with their covering of podocytes, are more permeable to water than other capillary beds in the body are.

The renal tubules convert glomerular filtrate to urine

The composition of the filtrate that enters the renal tubule is similar to that of the blood plasma, with the exception of high-molecular-weight solutes such as proteins. Reabsorption and secretion cause the composition of this fluid to change as it passes down the renal tubule. Cells of the tubule actively reabsorb certain molecules from the tubule fluid (which are returned to the blood flowing through the peritubular capillaries). For example, glucose and amino acids are reabsorbed. Most NaCl is reabsorbed. Other substances in the blood of the peritubular capillaries are actively secreted into the tubule fluid. An example is paraaminohippuric acid (PAH), which is produced in the liver from benzoic acid, a common food preservative. Because of the actions of the renal tubules, the excreted urine is very different from the original filtrate.

RECAP 52.4

The kidney is the major excretory organ of vertebrates. Its functional unit is the nephron, which includes a glomerulus that filters blood and a renal tubule that secretes and reabsorbs solutes, modifying the filtrate to produce urine. The nephron is a mechanism for excreting excess water while conserving valuable solutes.

- Explain the differences in the osmoregulatory adaptations of freshwater fish, marine bony fish, and chondrichthyans. **See p. 1077**
- What are the functional relationships between the glomerular and peritubular capillaries? **See p. 1078 and Figure 52.7**
- Describe how blood is filtered by the glomerulus. **See pp. 1078–1079**
- How is the composition of the urine made different from the composition of the blood? **See p. 1079**

The adaptations that enable the mammalian kidney to produce urine more concentrated than extracellular fluids were important steps in vertebrate evolution, and they were largely achieved through changes in the structure and regional functions of the renal tubules. These changes converted a kidney that evolved to excrete water into an organ that conserves water.

52.5 How Does the Mammalian Kidney Produce Concentrated Urine?

Mammals have high body temperatures and high metabolic rates, and therefore have the potential for a high rate of water

52.9 The Human Excretory System (A) The human kidneys lie against the back wall of the abdominal cavity, in the region of the middle back. (B) A highly organized internal structure is the basis for kidney function. Certain parts of the nephrons are in the organ's outer region, called the cortex; other parts are in the internal region, called the medulla. (C) The glomeruli and the proximal and distal convoluted tubules are located in the cortex of the kidney. The

loops of Henle run in parallel as straight sections down into the renal medulla and back up to the cortex. Collecting ducts run from the cortex to the inner surface of the medulla, where they open into the ureter. The vasa recta are peritubular capillaries that parallel the loops of Henle.

Kidneys produce urine and the bladder stores it

Mammalian excretory systems are similar, so we will use that of humans as our example. Humans have two kidneys at the back of the upper region of the abdominal cavity (**Figure 52.9A**). Each kidney filters blood, processes the filtrate into urine, and releases that urine into a duct called the **ureter**. The

ureter of each kidney leads to the **urinary bladder**, where the urine is stored until it is excreted through the **urethra**, a short tube that opens to the outside of the body.

Two sphincter muscles surrounding the base of the urethra control urination. One of these sphincters is a smooth muscle and is controlled by the autonomic nervous system. As the bladder fills, stretch receptors in the walls of the bladder trigger a spinal reflex that relaxes this sphincter. This reflex is the only control of urination in infants, hence their frequent “accidents.” The other sphincter is a skeletal muscle and is controlled by the voluntary nervous system. When the bladder is *very* full, only deliberate conscious effort prevents urination. Toilet training of children teaches them to control this sphincter.

WORKING WITH DATA:

What Kidney Characteristics Determine Urine Concentrating Ability?

Original Paper

Schmidt-Nielsen, B. and R. O'Dell. 1961. Structure and concentrating mechanism in the mammalian kidney. *American Journal of Physiology* 200: 1119–1124

Analyze the Data

In the 1950s it was hypothesized that the loops of Henle in mammalian kidneys are a countercurrent multiplier mechanism responsible for the ability of mammals to concentrate their urine. Bodil Schmidt-Nielsen and Roberta O'Dell extended this hypothesis to make a prediction: the longer the loops of Henle, the greater the concentration gradient a mammal could establish. There was a problem with their prediction, however. Since kidney size varies with body size, it presumes that a very small mammal could not have loops of Henle longer than those of a large mammal—yet many mammals that inhabit arid environments (and thus need to conserve water by producing highly concentrated urine) are extremely small. Schmidt-Nielsen and O'Dell refined their prediction to say that the *relative* lengths of the loops of Henle should correlate with ability to concentrate urine. Since the longest loops of Henle can only be as long as the renal medulla is thick, they conceived of a measure they called “relative medullary thickness,” or RMT (see the table).

Another possibility existed, however. As can be seen in Figure 52.9C, not all loops of Henle extend all the way to the tip of the medulla—there are short and long loops of Henle. Could the concentrating ability of the kidney be a function of the *proportion* of the loops that are long? Schmidt-Nielsen and O'Dell measured aspects of kidney size and function in several animals from habitats of different aridity and determined the maximum concentration of urine the animals could produce when water-deprived. Some of their data are summarized in the table below.

QUESTION 1

Is the length of the loops of Henle relative to overall kidney size predictive of ability to concentrate urine? (To answer this, plot RMT versus FPD.)

QUESTION 2

Are animals with a higher percentage of long loops of Henle more capable of producing concentrated urine? (Plot percent long loops of Henle versus FPD.)

QUESTION 3

Is percent long loops of Henle or RMT the better predictor of concentration ability?

Animal	Kidney size (mm) ^a	Relative medullary thickness, RMT ^b	Percent long loops of Henle	Freezing point depression, FPD (°C) ^c
Human	64.0	3.0	14	2.6
Pig	66.0	1.6	3	2.0
Domestic cat	24.0	4.8	100	5.80
Beaver	36.0	1.3	0	0.96
Lab rat	14.0	5.8	28	4.85
Sand rat	13.0	10.7	100	9.2
Kangaroo rat	5.9	8.5	27	10.4
Jerboa	4.5	9.3	33	12.0

^aKidney size = cube root of overall length × width × thickness

^bRMT = thickness of medulla in mm × 10 divided by kidney size.

^cFPD = the number of degrees below 0°C at which urine freezes. FPD is a measure of solute concentration: the more concentrated the urine, the higher the FPD.

Nephrons have a regular arrangement in the kidney

The kidney is shaped like a kidney bean; when sliced along its long axis, its key anatomical features are revealed (**Figure 52.9B**). The ureter and the **renal artery** and **renal vein** enter the kidney on its concave (punched-in) side. The ureter extends into the kidney in several branches, the ends of which envelop kidney tissues called **renal pyramids**. The renal pyramids make up the internal core, or **medulla**, of the kidney. The medulla is covered by an outer layer, or **cortex**, that has a granular appearance. Between the cortex and the medulla, the renal artery divides into the many arterioles that serve the nephrons. In this same region, the renal vein collects blood from the many venules that drain the peritubular capillaries.

The organization of the nephrons within the kidney is very regular. All of the glomeruli with their Bowman's capsules are located in the cortex. The initial segment of a renal tubule is

called the **proximal convoluted tubule**—“proximal” because it is closest to the glomerulus, and “convoluted” because it is twisted (**Figure 52.9C**). All of the proximal convoluted tubules are also located in the cortex.

At the point at which the renal tubule descends into the medulla, it becomes thin, straightens, and descends directly down into the medulla. In the medulla the tubule makes a hairpin turn and ascends back to the cortex, forming what is called the **loop of Henle**. Some nephrons have longer loops of Henle than others. Some 20 to 30 percent of human nephrons that have glomeruli deep in the cortex (i.e., near the border with the medulla) have long loops of Henle that go deep into the medulla. Nephrons that have glomeruli farther up in the cortex generally have short loops of Henle that descend only a short distance into the medulla. As we will see, the long loops are the critical adaptation of the mammalian nephron that enables the kidney to concentrate the urine.

The ascending limb of the loop of Henle becomes the **distal convoluted tubule** when it reaches the cortex—“distal” because it is farther from the glomerulus. The distal convoluted tubules of many nephrons join a common **collecting duct** in the cortex. The collecting ducts descend back down through the renal pyramid, parallel to and past the tips of the loops of Henle, and empty into a funnel-shaped structure called the pelvis. Divisions of the pelvis that surround each renal pyramid join together to leave the kidney as the ureter (see Figure 52.9B).

The organization of the blood vessels of the kidney closely parallels the organization of the nephrons (see Figure 52.9C). Smaller arteries branch from the renal artery and radiate into the cortex, forming the afferent arterioles that carry blood to each glomerulus. Each glomerulus is drained by an efferent arteriole that gives rise to the peritubular capillaries, most of which surround the proximal and distal convoluted tubules. As we have seen, the intimate associations of the glomerular and peritubular capillaries with the renal tubules permit exchanges between the blood and the specialized regions of the tubules.

Some of the peritubular capillaries run into the medulla in parallel with the loops of Henle and the collecting ducts, forming a vascular network called the **vasa recta**. All of the peritubular capillaries from a nephron join back together into a venule that joins with venules from other nephrons and eventually leads to the renal vein. As we will see, the concentrating ability of the mammalian kidney depends on water reabsorption in the renal medulla, and the vasa recta are the avenue by which that water gets out of the renal medulla and back into the circulation.

Most of the glomerular filtrate is reabsorbed by the proximal convoluted tubule

Most of the water and solutes filtered by the glomerulus are reabsorbed and do not appear in the urine. We can reach this conclusion by comparing the rate of filtration by the glomeruli with the rate of urine production. The kidneys receive about 1 liter of blood per minute, or about 1,500 liters of blood per day. How much of this huge volume is filtered out of the glomeruli? The answer is about 12 percent. This is still a large volume—180 liters per day! We normally urinate less than 2 liters per day, so about 99 percent of the fluid volume that is filtered out of the glomerulus is returned to the blood. Where and how is this enormous fluid volume reabsorbed?

The proximal convoluted tubule (PCT) is responsible for most of the reabsorption of water and solutes from the glomerular filtrate. The cells of this section of the renal tubule have many microvilli that increase their apical (facing into the tubule) surface area for reabsorption, and they have many mitochondria—an indication that they are metabolically active. PCT cells actively transport Na^+ (with Cl^- following) and other solutes, such as glucose and amino acids, out of the tubule fluid.

Almost all glucose and amino acid molecules that are filtered from the blood are actively reabsorbed by PCT cells and transported into the extracellular fluid. The active transport of solutes from the proximal tubule into the interstitial fluid

causes water to follow osmotically. The water and solutes moved into the interstitial fluid are taken up by the peritubular capillaries and returned to the venous blood. These processes accomplish the reabsorption of more than 75 percent of the fluid that initially enters the nephron.

Despite the bulk reabsorption of water and solutes by the proximal convoluted tubule, the overall osmolarity of the fluid flowing through the PCT does not change. Thus the process that is occurring in the PCT is called **isosmotic reabsorption**. The fluid that enters the loop of Henle has the same osmolarity as the blood plasma, although its composition is different. How then does the kidney produce urine that is more concentrated than the blood plasma?

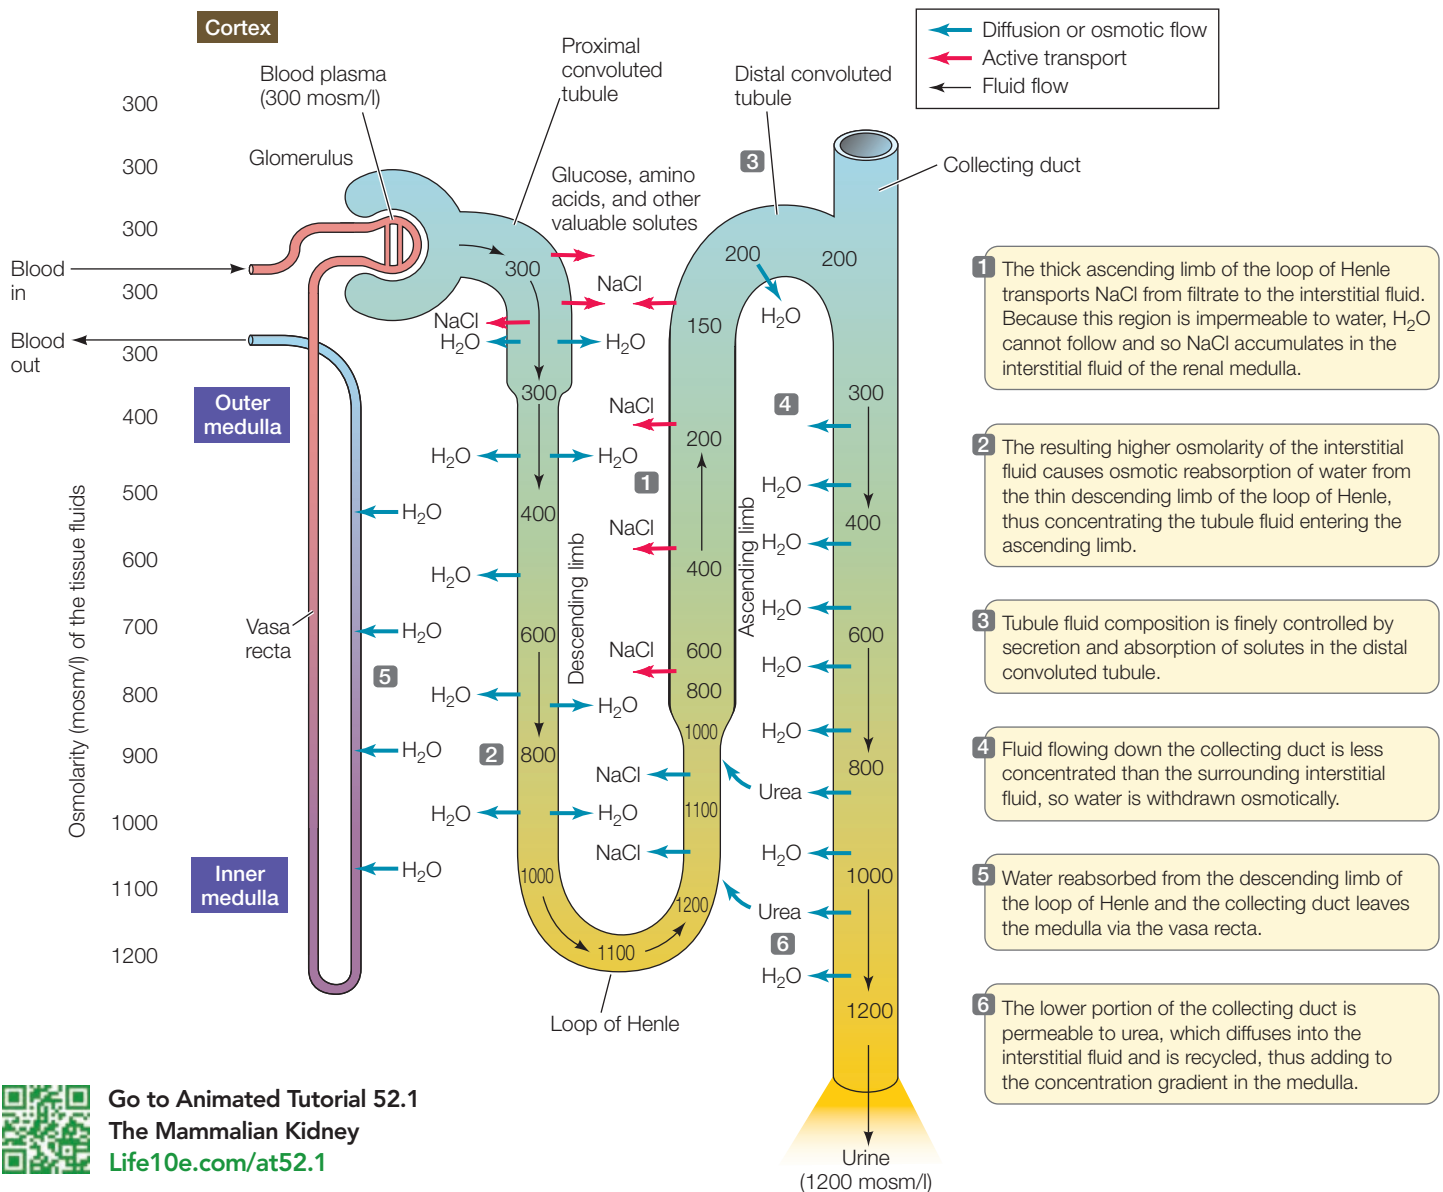

The loop of Henle creates a concentration gradient in the renal medulla

Humans can produce urine that is four times more concentrated than their blood plasma. The vampire bat we encountered at the beginning of this chapter can produce urine that is 15 times more concentrated than its blood plasma. The concentrating ability of the mammalian kidney arises from a **counter-current multiplier** mechanism made possible by the anatomical arrangement of the loops of Henle. The term “countercurrent” refers to the opposing directions in which the tubule fluid in the descending and ascending limbs flows. The term “multiplier” refers to the ability of this system to create a solute concentration gradient in the renal medulla.

The loops of Henle do not themselves produce concentrated urine; rather, they increase the osmolarity of the extracellular fluid in the medulla in a graduated way. In humans, for example, the extracellular fluid at the top of the medulla bordering the cortex will be about 300 mosm/L (the concentration of blood plasma). But at the bottom of the medulla, where the loops of Henle make their hairpin turns, the extracellular fluid can be 1,200 mosm/L (see Figure 52.10). How do the loops produce this effect?

The cells that make up the different segments of the loop of Henle differ anatomically and functionally. Cells of the descending limb and the initial cells of the ascending limb are thin, with no microvilli and few mitochondria. They are not specialized for transport. Partway up the ascending limb, the cells become specialized for active transport. These cells are thick and have many mitochondria. Accordingly, the segments of the loop of Henle are named the thin descending limb, the thin ascending limb, and the thick ascending limb (**Figure 52.10**).

The countercurrent multiplier mechanism may be more easily understood by first considering events occurring in the thick ascending limb (Figure 52.10, note 1). The cells of the thick ascending limb reabsorb Na^+ and Cl^- from the tubule fluid and move it into the interstitial fluid. (In the following discussion, we will distinguish between the two components of extracellular fluid—the blood plasma and the interstitial fluid.) The thick ascending limb is not permeable to water, so the reabsorption of Na^+ and Cl^- from the tubular fluid raises the concentration of those solutes in the surrounding interstitial fluid

The Mammalian Kidney
Life10e.com/at52.1

52.10 Concentrating the Urine A countercurrent multiplier mechanism enables the mammalian kidney to produce urine that is far more concentrated than the blood plasma. The composition—but not the concentration—of the filtrate is changed by the proximal convoluted tubule, which reabsorbs valuable molecules (including NaCl). Bulk reabsorption of water follows osmotically. The urine concentration pro-

cess begins in the thick ascending limb of the loop of Henle, which reabsorbs NaCl but is impermeable to H₂O. Some of the reabsorbed NaCl enters the descending limb and is thereby trapped in the renal medulla, creating a concentration gradient in the interstitial fluid. As urine in the collecting duct passes through this concentration gradient, it can lose water osmotically and become highly concentrated.

and decreases the concentration of the tubular fluid entering the distal convoluted tubule.

The thin descending limb, in contrast, is highly permeable to water but not very permeable to Na⁺ and Cl⁻. Since the local interstitial fluid has been made more concentrated by the Na⁺ and Cl⁻ reabsorbed from the neighboring thick ascending limb, water is withdrawn osmotically from the fluid in the descending limb. Therefore the fluid in the descending limb becomes more concentrated as it flows toward the hairpin turn at the bottom of the renal medulla (Figure 52.10, note 2).

The thin ascending limb, like the thick ascending limb, is not permeable to water. It is, however, permeable to Na⁺ and Cl⁻. As the concentrated tubule fluid flows up the thin ascending limb, it is more concentrated than the surrounding interstitial fluid, so Na⁺ and Cl⁻ diffuse out. When the tubule fluid reaches the thick ascending limb, active transport continues to move Na⁺ and Cl⁻ from the tubule fluid to the interstitial fluid.

As a result of the processes described above, the tubule fluid reaching the distal convoluted tubule is less concentrated than the blood plasma (Figure 52.10, note 3), and the solutes

that have been left behind in the renal medulla have created a concentration gradient in the interstitial fluid of the medulla (indicated by the background color gradient in Figure 52.10).

You may wonder why the blood flow through the medulla does not wash out the concentration gradient established by the loops of Henle. The parallel arrangement of the descending and ascending peritubular capillaries—the vasa recta—in the medulla helps preserve the concentration gradient in the medulla. These capillaries are permeable to both salt and water. Therefore, as blood flows down the descending limb of the vasa recta into the increasingly concentrated interstitial fluid of the medulla, it loses water and gains solutes. As blood flows up from the bottom of the medulla in the ascending limb of the vasa recta, the opposite happens (water is gained and solutes are lost) because now the blood is more concentrated than the surrounding interstitial fluid (Figure 52.10, notes 4–6). The dynamics of this countercurrent exchange of salts and water between the blood in the vasa recta and the interstitial fluids result in little net change in the composition of the interstitial fluid in the medulla.

Water permeability of kidney tubules depends on water channels

We have noted that some tubule regions, such as the PCT, are highly permeable to water whereas others, such as the thick ascending limb of the loop of Henle, are impermeable to water. What causes these differences in water permeability in different regions of the nephron? Aquaporins are a class of membrane proteins that form water channels (see Section 6.3). Regions of the nephron that are highly permeable to water have greater numbers of aquaporins. Thus aquaporins are abundant in kidney PCT cells and in descending limbs of the loops of Henle, but not in the ascending limbs of the loop of Henle.

As an interesting evolutionary note, aquaporins are also important in maintaining water balance in amphibians. When not in an aqueous environment, many amphibians can gain water from a moist substrate because they have aquaporins in the epithelial cells of their belly skin. Thus water can cross their skin into the interstitial fluid by osmosis.

The distal convoluted tubule fine-tunes the composition of the urine

The first portion of the distal convoluted tubule is similar to the thick ascending limb of the loop of Henle. Na^+ and Cl^- are transported out of the tubule fluid, and water cannot follow. As a result, the tubule fluid becomes even more dilute. The later sections of the distal convoluted tubule, however, can be permeable to water, and water can be osmotically drawn from the tubule into the interstitial fluid. As the tubule fluid flows from the distal tubule to the collecting duct, it can be below or equal to the osmolarity of the blood plasma.

An important function of the distal tubule is the fine-tuning of the ionic composition of the urine. Even though bulk reabsorption of substances such as calcium, phosphate, bicarbonate, and potassium occurs in the proximal convoluted tubule, changes in the concentrations of these substances occur in the

distal convoluted tubule. In the case of potassium, for example, if a person is potassium depleted, this ion is reabsorbed in the distal convoluted tubule, but if a person has an abundance of potassium, this ion is secreted in the distal convoluted tubule. As we will see below, this exchange of K^+ is controlled by the hormone aldosterone. Another example is reabsorption of Ca^{2+} in the distal convoluted tubule, which is controlled by the actions of vitamin D. The fine-tuning of urine composition continues in the collecting duct. As you can imagine, the list of ion transporters in the distal convoluted tubule is large.

Urine is concentrated in the collecting duct

The tubule fluid entering the collecting duct is at about the same solute *concentration* as the blood plasma, but its solute *composition* is considerably different from that of the plasma. The major solute in the tubular fluid is now urea, since salts were reabsorbed earlier in the nephron. As the tubule fluid flows down the collecting duct, it loses water osmotically to the interstitial fluid, and that water returns to the circulatory system via the vasa recta (see Figure 52.10, note 4).

The concentration gradient established in the renal medulla by the countercurrent multiplier actions of the loops of Henle creates the osmotic potential that withdraws water from the collecting ducts. The collecting ducts begin in the renal cortex and run through the renal medulla before emptying into the ureter at the tips of the renal pyramids. During this journey, the solute concentration of the surrounding interstitial fluid increases, and more and more water can be absorbed from the urine in the collecting duct. By the time it reaches the ureter, the urine can become greatly concentrated, with urea as the major solute.

As water is withdrawn from the collecting duct, some urea also leaks out into the medullary interstitial fluid, adding to its osmotic potential. This urea diffuses back into the loop of Henle and is returned to the collecting duct. The recycling of urea in the renal medulla contributes significantly to the concentration gradient and therefore the ability of the kidney to concentrate the urine in the collecting duct. The ability of a mammal to concentrate its urine is determined by the maximum concentration gradient it can establish in its renal medulla.

The kidneys help regulate acid–base balance

Besides regulating salt and water balance and excreting nitrogenous wastes, the kidneys have another important role: they regulate the hydrogen ion concentration (the pH) of the extracellular fluids. pH is a critical variable because it influences the structure and function of proteins.

One way to minimize pH changes in a chemical solution is to add a buffer—a substance that can either absorb or release hydrogen ions (see Section 2.4). The major buffer in the blood is bicarbonate ions (HCO_3^- ; see Figure 49.14) that are formed from the dissociation of carbonic acid, which in turn is formed by the hydration of CO_2 according to the following equilibrium reaction:

52.11 The Kidney Excretes Acids and Conserves Bases (A) Bicarbonate ions are filtered out of the blood at the glomerulus, and renal tubule cells secrete hydrogen ions into the tubule fluid. In the renal tubule, the filtered bicarbonate buffers the secreted hydrogen ions and keeps the urine from becoming too acidic. The CO_2 formed by

the reaction of bicarbonate and hydrogen ions is converted back to bicarbonate by the renal tubule cells and transported back into the interstitial fluid. (B) Excretion of ammonia (NH_3) by renal tube cells is also important for acid–base balance.

From this equation, you can see that if excess hydrogen ions are added to this reaction mixture, the reaction will move to the left and absorb the excess H^+ . If hydrogen ions are removed from the reaction mixture, however, the reaction will move to the right and supply more H^+ .

The HCO_3^- buffer system is important for controlling the pH of the blood, and therefore of the interstitial fluids as well, because the reaction can be pushed to the right and pulled to the left physiologically. The lungs control the levels of CO_2 in the blood, thus altering the acid portion of the reaction. CO_2 is considered the acid portion of the reaction because if you add additional CO_2 , the reaction shifts to the right, producing more H^+ ions. The kidneys control the base portion of the reaction by removing H^+ from the blood and returning HCO_3^- to the blood. How does this occur?

HCO_3^- is filtered in the glomerulus and is therefore present in the tubular fluid. Tubule cells transport H^+ into the tubule fluid in exchange for Na^+ . In the tubule, the excreted H^+ combines with the filtered HCO_3^- to produce H_2CO_3 that then dissociates into H_2O and CO_2 . The CO_2 diffuses into the tubule cells, where in the presence of the enzyme carbonic anhydrase it produces HCO_3^- that is transported out of the basal end of

the cell into the interstitial fluid and thence to the blood (Figure 52.11A). Thus for each H^+ secreted into the tubule fluid, a HCO_3^- ion is released into the blood.

Another mechanism for H^+ secretion and HCO_3^- reabsorption involves ammonia (NH_3). The metabolism of glutamine in tubule cells produces NH_3 and HCO_3^- (Figure 52.11B). The HCO_3^- is reabsorbed into the interstitial fluid. The NH_3 is transported into the tubule fluid and combines with H^+ to form ammonium (NH_4^+), which is excreted in the urine. This process results in the net excretion of H^+ from the body. The NH_3 is transported into tubules by means of an NH_3 transporter that has been characterized recently in an effort to identify novel proteins coming from the sequencing of the human and other genomes (Figure 52.12).

Kidney failure is treated with dialysis

Loss of kidney function (renal failure) results in the retention of salts and water (hence high blood pressure), retention of urea (uremic poisoning), and a decreasing pH (acidosis). A person who suffers complete renal failure will die within 2 weeks if not treated. A drastic but highly successful treatment is kidney transplant, but it is usually necessary to sustain a patient for

INVESTIGATINGLIFE

52.12 An Ammonium Transporter in the Renal Tubules?

An important way the kidney excretes hydrogen ions and buffers the blood is to secrete ammonia (NH_3) into the renal tubules. It was thought that ammonia simply diffused into the

tubules until the function of Rhcg, a protein in the Rh blood antigen family was discovered. This experiment demonstrated that loss of the *Rhcg* gene in mice impairs their ability to buffer their blood pH by excreting excess H^+ (in the form of ammonium)^a

HYPOTHESIS The protein Rhcg is an ammonia transporter and is critical for the kidney's role in acid–base balance.

Method

1. Create a line of mice in which the gene for the protein Rhcg is knocked out (see Section 18.4).
2. Measure starting blood pH, plasma bicarbonate (HCO_3^-) levels, and urine ammonium (NH_4^+) levels in experimental and control (wild-type) mice.
3. For 6 days, administer drinking water containing a mild acid to control mice and to Rhcg knockout mice.
4. Measure the three variables (see item 2 above) at days 2 and 6.

Results

CONCLUSION Lack of functional Rhcg protein impairs a mouse's ability to secrete ammonium ions in its urine, thus limiting the capacity to regulate acid–base balance. This protein is probably an ammonia transporter in the renal tubules.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

Biver, S. et al. 2008. *Nature* 456: 339–343.

considerable time while waiting for a kidney to become available. Therefore artificial kidneys, or renal dialysis machines, are essential modes of treatment.

In a dialysis machine, the patient's blood flows through many small channels made of semipermeable membranes (**Figure 52.13**). A dialysis solution flows on the other side of these membranes, through which small molecules can diffuse. Molecules and ions diffuse from an area of higher concentration to an area of lower concentration, so the composition of the dialysis fluid is crucial. The concentrations of the molecules or ions that need to be conserved must be at the same concentration in the dialysis fluid as they are in the blood. The concentrations of molecules and ions that need to be removed from the blood are zero in the dialysis fluid. The total osmotic potential of the dialysis fluid must equal that of the plasma.

About 500 ml of the patient's blood is in the dialysis machine at any one time, and the unit processes several hundred milliliters of blood per minute. A patient with no kidney function must be on the dialysis machine for 4 to 6 hours three times a week.

RECAP 52.5

The anatomical organization of nephrons makes it possible for the mammalian kidney to produce a urine more concentrated than the blood, thereby conserving water to maintain extracellular fluid volume. Bulk reabsorption of salts, other valuable solutes, and water takes place in the proximal convoluted tubule. The loops of Henle act as a countercurrent multiplier, creating a concentration gradient of the interstitial fluids in the renal medulla. Collecting ducts run through the renal medulla and lose water osmotically to the surrounding interstitial fluids, concentrating the urine.

- Explain how the countercurrent multiplier mechanism of the nephron makes it possible for the kidney to form a concentrated urine. **See pp. 1082–1083 and Figure 52.10**
- Why doesn't the blood flow through the kidney wash out the concentration gradient in the medulla? **See p. 1082 and Figure 52.10**
- How does the kidney contribute to acid–base balance? **See pp. 1085–1086 and Figures 52.11 and 52.12**

52.13 Renal Dialysis Patients with kidney failure can have their blood cleansed of wastes by renal dialysis machines. Blood flows through channels of semipermeable membranes that allow diffusion of waste molecules from the blood to a dialysis fluid.

The kidney contributes to homeostasis in several ways, including regulating extracellular fluid volume, maintaining the osmotic concentration and ionic composition of the extracellular fluid, and regulating pH. As we will see next, the kidneys also play a major role in regulating blood pressure.

52.6

How Are Kidney Functions Regulated?

Several regulatory mechanisms act on the kidneys to maintain blood pressure, blood osmolarity, and blood composition. We will discuss these mechanisms separately, but keep in mind that they are always working together.

Glomerular filtration rate is regulated

If the kidneys stop filtering blood, they cannot accomplish any of their functions. The maintenance of a constant **glomerular filtration rate (GFR)** depends on an adequate blood supply to the kidneys at an adequate blood pressure. Renal arteries usually deliver blood to the kidneys at high pressure because they are early branches off the aorta. In addition, autoregulatory mechanisms ensure adequate blood supply and blood pressure for kidney function regardless of what is happening elsewhere in the body. The kidney's autoregulatory adjustments compensate for decreases in cardiac output or decreases in blood pressure so that the GFR remains constant.

One autoregulatory mechanism is the dilation (expansion) of the afferent renal arterioles when blood pressure falls. This dilation decreases the resistance in the arterioles and helps maintain blood pressure in the glomerulus. If arteriole dilation does not keep the GFR from falling, the kidney releases an enzyme, **renin**, into the blood. Renin converts a circulating protein, angiotensinogen, into angiotensin I, which is then acted on by angiotensin-converting enzyme (ACE) to form the active hormone angiotensin II, or simply **angiotensin** (Figure 52.14). Angiotensin has several effects that help restore the GFR to normal:

- It constricts the efferent renal arterioles, raising the resistance for blood leaving the glomerulus. Like putting a finger over the end of a garden hose, this restriction of drainage elevates blood pressure in the glomerular capillaries.
- It constricts peripheral blood vessels all over the body, an action that elevates blood pressure.
- It stimulates the adrenal cortex to release the hormone **aldosterone**. Aldosterone stimulates sodium reabsorption by the kidney, making its reabsorption of water more effective. Enhanced water reabsorption helps maintain blood volume and therefore blood pressure.
- It acts on the brain to stimulate thirst. Increased water intake in response to thirst increases blood volume and blood pressure.

Thus the renin-angiotensin-aldosterone system, or RAAS, coordinates many responses to maintain blood pressure and kidney function.

Regulation of GFR uses feedback information from the distal tubule

A remarkable anatomical feature of the nephron is that where its renal tubule returns to the cortex and becomes the distal

convoluted tubule, it makes contact with the afferent and efferent arterioles of its glomerulus. At this location the cells of the tubule are modified to form a structure called the macula densa (see Figure 52.14), and the arteriole cells are also modified and are called juxtaglomerular cells. The macula densa cells sense the concentration of NaCl in the fluid entering the distal convoluted tubule. If glomerular filtration rate is high, flow through the loop of Henle is high and the cells of the thick ascending limb cannot reabsorb all of the NaCl passing through it. If GFR is low, flow through the loop of Henle is slower and the cells of the thick ascending limb can reabsorb more of the NaCl. If the NaCl level in the distal convoluted tubule drops too low, the macula densa cells signal the juxtaglomerular cells to release renin and trigger the RAAS response. Thus the concentration of NaCl in the fluid passing over the macula densa is a function of the GFR and is information that enables fine control of the RAAS system.

Blood osmolarity and blood pressure are regulated by ADH

Cells in the hypothalamus can stimulate the release of a hormone called **antidiuretic hormone (ADH)**, also called vasopressin) from the posterior pituitary. ADH can act on cells of the

collecting duct to insert aquaporins (water channels) into their plasma membranes. The aquaporins increase the permeability of these membranes to water, and therefore more water is reabsorbed from the collecting duct fluid into the interstitial spaces of the renal medulla. The higher the circulating levels of ADH, the greater the number of aquaporins. Various factors can stimulate or inhibit the release of ADH. Of key importance to kidney function are osmoreceptors that monitor blood osmolarity and stretch receptors that monitor blood pressure (**Figure 52.15**).

Osmoreceptor neurons in the hypothalamus are activated by a rise in blood osmolarity, and they increase the release of ADH. ADH helps regulate blood osmolarity by controlling water reabsorption. The osmoreceptors also stimulate thirst. The resulting water retention and water intake dilute the blood as they expand blood volume.

Stretch receptors in the walls of the aorta and the carotid arteries (see Figure 50.19) that detect an increase in blood pressure will *inhibit* the release of ADH. With less circulating ADH, less water is reabsorbed, which decreases blood volume and hence acts to lower blood pressure.

If blood pressure falls, as when you lose blood volume through hemorrhage or excessive evaporative water loss,

52.15 Antidiuretic Hormone Increases Blood Pressure and Promotes Water Reabsorption ADH is produced by neurons in the hypothalamus and released from nerve endings in the posterior pituitary. The release of ADH is stimulated by hypothalamic osmoreceptors and inhibited by stretch receptors in the great arteries. Red lines indicate inhibitory actions; green lines show stimulatory actions.

activity of the stretch receptors in the aorta and carotid arteries decreases. Input via cranial nerves to the hypothalamus from these receptors inhibits the release of ADH, so when the firing rates of these stretch receptors fall, ADH release increases. More ADH results in more efficient water reabsorption and therefore a protection of blood volume and blood pressure.

Alcohol inhibits ADH release, explaining why excessive beer drinking leads to excessive urination and dehydration, which contributes to the symptoms of a hangover.

As mentioned earlier, the presence of aquaporins in plasma membranes determines their water permeability. Aquaporins play an important and unique role in the collecting duct. Several members of the aquaporin family of water channels are found in the plasma membranes of cells in the distal tubules. At least two aquaporins (AQP-3 and AQP-4) are localized in the basolateral membranes (facing the blood vessels). A different aquaporin, called AQP-2, is found in the apical plasma membranes (facing into the tubule). The presence of AQP-2 in these membranes is controlled by ADH, as described in **Figure 52.16**.

INVESTIGATINGLIFE

52.16 ADH Induces Insertion of Aquaporins into Plasma Membranes

Aquaporin proteins make some regions of renal tubules permeable to water. One aquaporin, AQP-2, is responsible for the permeability of the collecting duct cells. M. A. Knepper and colleagues did an experiment to find out how antidiuretic hormone acts on these proteins to control the level of permeability in renal cells.^a

HYPOTHESIS Antidiuretic hormone (ADH) controls the location of aquaporin proteins.

Method

1. Isolate collecting ducts from rat kidney.
2. Use immunochemical staining to localize the AQP-2 aquaporins in collecting duct cells both with and without the presence of ADH. Also localize the aquaporins after ADH is applied and then washed away.

3. Measure the water permeability of the collecting duct cells under the same three conditions.

Results

CONCLUSION In the absence of ADH, AQP-2 is sequestered intracellularly. When ADH is present, AQP-2 channels are inserted into the plasma membranes, making the cells more permeable to water.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATINGLIFE** figures.

^aNielsen, S. et al. 1995. *Proceedings of the National Academy of Sciences USA* 92: 1013–1017.

When ADH levels are low, such as when a person is well hydrated, most of the AQP-2 protein is sequestered in the membranes of intracellular vesicles, and the collecting duct permeability is low. A rise in ADH levels stimulates the insertion of these vesicles along with their AQP-2 channels into the apical plasma membranes. As a result, the membranes become more permeable to water. Water that enters the collecting duct cells passes into the interstitial fluid through the aquaporins in the basolateral membranes. ADH also stimulates the synthesis of new AQP-2 proteins. Thus circulating ADH controls the number of AQP-2 water channels in the plasma membranes of the collecting duct cells, and therefore the permeability of the collecting duct to water.

The heart produces a hormone that helps lower blood pressure

You may not think of the heart as an endocrine organ, but it is. When blood volume is high, blood pressure is high, putting strain on the heart. Under these conditions, the increased venous return stretches the atria of the heart. When the atrial muscle fibers are overly stretched, they release a peptide hormone called **atrial natriuretic peptide (ANP)**. This peptide hormone enters the circulation, and in the kidney it decreases the reabsorption of sodium. If less sodium is reabsorbed, less water is reabsorbed, and more passes into the urine. Thus ANP has the effect of lowering blood volume and therefore blood pressure.

RECAP 52.6

Glomerular filtration is essential for kidney function and is sustained by autoregulatory mechanisms. Sensors that monitor blood pressure and blood osmolarity may stimulate or inhibit the release of hormones that regulate kidney function.

- Explain how falling GFR results in an increase in circulating angiotensin and how angiotensin restores GFR. **See pp. 1087–1088 and Figure 52.14**
- Explain how falling blood pressure or increasing blood osmolarity results in changes in permeability of the collecting ducts. **See Figure 52.15**

(A) Desert gerbil

(B) Laboratory rat

52.17 The Ability to Concentrate The ability of the mammalian kidney to concentrate urine depends on the lengths of its loops of Henle relative to the overall size of the kidney. (A) The kidney of a desert gerbil has a single renal pyramid with loops of Henle so long that the pyramid extends far into the ureter (ureter not shown). (B) An ordinary laboratory rat has much shorter loops of Henle.

How do desert rodents and vampire bats make highly concentrated urine?

ANSWER

As we described in the opening story, some desert rodents and vampire bats conserve water by producing urine that can be as much as 15 times more concentrated than their blood. In fact, the urine is so concentrated that it contains crystals of solute. For comparison, the maximum urine concentration of humans is about four times that of the blood.

Recall from Section 52.5 that the mammalian body's ability to produce concentrated urine depends on the concentration gradient set up in the renal medulla by the loops of Henle. An important adaptation for increasing the concentration gradient is to increase the lengths of the loops of Henle relative to over-

all kidney size. Some tiny desert gerbils, for example, have such extremely long loops of Henle that the renal pyramid (each of the rodent kidneys has only one, in contrast to humans) extends far out of the concave surface of the kidney and into the ureter (**Figure 52.17**). The large concentration gradient that results draws most of the water out of the urine as it passes down the collecting duct. Desert gerbils are so effective in conserving water that they can survive on the water released by the metabolism of their food. The vampire bat kidney is particularly good at concentrating urea. Within minutes after feeding, the urea concentration in its urine can increase by more than 500-fold.

52.1 How Do Excretory Systems Maintain Homeostasis?

- **Excretory systems** maintain the osmolarity and volume of the extracellular fluids and eliminate the waste products of nitrogen metabolism through the processes of filtration, reabsorption, and secretion. **Urine** is the output of excretory systems.
- There is no active transport of water, so water must be moved across membranes by a difference in either **osmolarity** or pressure.
- Water enters and leaves cells by osmosis. To achieve cellular water balance, animals must maintain the osmolarity of their extracellular fluids within an acceptable range.
- Marine animals can be **osmoconformers** or **osmoregulators**. Freshwater animals must be osmoregulators and must continually excrete water and conserve salts. Terrestrial animals are osmoregulators, but the nature of their regulation depends on environment and lifestyle.
- Apart from regulating osmolarity of cells and extracellular fluids, animals must also regulate their ionic composition by conserving some ions and secreting others. Salt glands are adaptations for secretion of NaCl. **Review Figure 52.2**

52.2 How Do Animals Excrete Nitrogen?

- Aquatic animals that breathe water can eliminate nitrogenous wastes such as **ammonia** by diffusion across their gill membranes. Terrestrial animals and some aquatic animals must detoxify ammonia by converting it to **urea** or **uric acid** before excretion. **Review Figure 52.3**
- Depending on the form in which they excrete their nitrogenous wastes, animals are classified as **ammonotelic**, **ureotelic**, or **uricotelic**.

52.3 How Do Invertebrate Excretory Systems Work?

- The **protonephridia** of flatworms consist of flame cells and excretory tubules. Extracellular fluid is filtered into the tubules, which process the filtrate to produce a dilute urine. **Review Figure 52.4**
- In annelid worms, blood pressure causes filtration of the blood across capillary walls. The filtrate enters the coelomic cavity, where it is taken up by **metanephridia**, which alter the composition of the filtrate by active transport mechanisms. **Review Figure 52.5, ACTIVITY 52.1**
- The **Malpighian tubules** of insects receive ions and nitrogenous wastes by active transport across the tubule cells. Water follows by osmosis. Ions and water are reabsorbed from the rectum, so the insect excretes semisolid wastes. **Review Figure 52.6**

52.4 How Do Vertebrates Maintain Salt and Water Balance?

- Marine bony fishes produce little urine. Chondrichthyans retain urea and TMAO, so the osmolarity of their body fluids remains close to that of seawater.
- Reptiles and birds have skin with low water permeability and excrete nitrogenous wastes as uric acid in a semisolid form.
- Mammals produce urine that is more concentrated than their extracellular fluids.

- The **nephron**, the functional unit of the vertebrate **kidney**, consists of a **glomerulus**, in which blood is filtered, a **renal tubule**, which use processes of active secretion and reabsorption to convert the glomerular filtrate into urine to be excreted, and a system of **peritubular capillaries**, which surround the tubule and support its functions of secretion and reabsorption. **Review Figure 52.7, ACTIVITY 52.2**

52.5 How Does the Mammalian Kidney Produce Concentrated Urine?

- The concentrating ability of the mammalian kidney is a function of its anatomy, which enables countercurrent exchange. **Review Figure 52.9**
- The glomeruli and the **proximal** and **distal convoluted tubules** are located in the **cortex** of the kidney. Certain molecules are actively reabsorbed from the glomerular filtrate by the tubule cells, and other molecules are actively secreted. Straight sections of renal tubules called **loops of Henle** and **collecting ducts** are arranged in parallel in the **medulla** of the kidney. **Review ACTIVITY 52.3**
- Salts, water, and valuable molecules such as glucose and amino acids are reabsorbed in the proximal convoluted tubule without the renal filtrate becoming more concentrated, although its composition changes.
- The loops of Henle create a concentration gradient in the interstitial fluid of the renal medulla by a **countercurrent multiplier** mechanism. Urine flowing down the collecting ducts to the **ureter** is concentrated by the osmotic reabsorption of water caused by the concentration gradient in the surrounding interstitial fluid. **Review Figure 52.10, ANIMATED TUTORIAL 52.1**
- Hydrogen ions secreted by the renal tubules are buffered in the urine by bicarbonate and other chemical buffering systems. **Review Figures 52.11, 52.12**

52.6 How Are Kidney Functions Regulated?

- Kidney function in mammals is controlled by autoregulatory mechanisms that maintain a constant high **glomerular filtration rate (GFR)** even if blood pressure varies.
- An important autoregulatory mechanism is the release of **renin** by the kidney when blood pressure falls. Renin activates **angiotensin**, which causes the constriction of efferent glomerular arterioles and peripheral blood vessels, causes the release of **aldosterone** (which enhances water reabsorption), and stimulates thirst. **Review Figure 52.14, ANIMATED TUTORIAL 52.2**
- Changes in blood pressure and osmolarity influence the release of antidiuretic hormone (ADH), which controls the permeability of the collecting duct to water and therefore the amount of water that is reabsorbed from the urine. ADH stimulates the expression of and controls the intracellular location of aquaporins, which serve as water channels in the membranes of collecting duct cells. **Review Figures 52.15, 52.16**
- When the volume of blood returning to the heart increases and stretches the atrial walls, **atrial natriuretic peptide (ANP)** is released, which causes increased excretion of salt and water.

CHAPTER REVIEW

REMEMBERING

- Which statement is *true*?
 - Most marine invertebrates are osmoregulators.
 - All freshwater invertebrates are osmoconformers.
 - Marine bony fish and chondrichthyans have similar extracellular osmolarities.
 - Freshwater fishes are ionic regulators.
 - Marine mammals gain water osmotically.
- The excretion of nitrogenous wastes
 - by humans can be in the form of urea and uric acid.
 - by mammals is never in the form of uric acid.
 - by marine fishes is mostly in the form of urea.
 - does not contribute to the osmolarity of the urine.
 - requires more water if the waste product is the rather insoluble uric acid.
- What is the role of renal podocytes?
 - They prevent red blood cells and large molecules from entering the renal tubules.
 - They reabsorb most of the glucose that is filtered from the plasma.
 - They control the glomerular filtration rate by changing the resistance of renal arterioles.
 - They provide a large surface area for tubular secretion and reabsorption.
 - They release renin when the glomerular filtration rate falls.
- Which part of the nephron is responsible for most of the difference in mammals between the glomerular filtration rate and the urine production rate?
 - The glomerulus
 - The proximal convoluted tubule
 - The loops of Henle
 - The distal convoluted tubule
 - The collecting duct
- Which of the following would *not* be a response stimulated by a large drop in blood pressure?
 - Constriction of afferent renal arterioles
 - Increased release of renin
 - Increased release of antidiuretic hormone
 - Increased thirst
 - Constriction of efferent renal arterioles

UNDERSTANDING & APPLYING

- Persons with uncontrolled diabetes mellitus can have very high levels of glucose in their blood. Why do such individuals have a high level of urine production?
- Patients with high blood pressure are sometimes treated with ACE inhibitors. Explain the rationale of this treatment.
- Inulin is a molecule that is filtered out of the glomerulus but is not secreted or reabsorbed by the renal tubules. If you injected inulin into an animal and after a brief time measured the concentration of inulin in the animal's blood and urine, how could you determine the animal's glomerular filtration rate? Assume that the rate of urine production is 1 milliliter per minute.

ANALYZING & EVALUATING

- After you did the inulin experiment to measure glomerular filtration rate, how could you use that information to determine whether another substance is secreted or reabsorbed by the renal tubules? Assume you can measure the concentration of that substance in the blood and urine. Urine production is still 1 milliliter per minute.
- Acetazolamide is a drug used by mountain climbers for short periods of time to help them acclimate to high altitude. The drug is an inhibitor of carbonic anhydrase. Referring back to Chapter 49, how do you think this drug helps in the acclimation process? In the context of this chapter, explain why a side effect of this drug is frequent urination.

- 53.4** How Does Behavior Evolve?
- 53.5** What Physiological Mechanisms Underlie Behavior?
- 53.6** How Does Social Behavior Evolve?

BROWN-HEADED COWBIRDS (*Molothrus ater*) are abundant and ubiquitous in North America, ranging over an enormous diversity of habitats. They are brood, or nest, parasites, laying their eggs in the nests of other species. A female cowbird may lay 40 eggs a season in as many different nests, but she never incubates her eggs or feeds her young. Cowbird eggs have been found in the nests of at least 220 other species. The host incubates the egg along with its own and feeds the young cowbird—often to the detriment of its own chicks because cowbird chicks are usually larger and more demanding.

Cowbirds have enormous reproductive success and it is not difficult to understand the evolution of brood parasitism from the standpoint of the parasite. But what about the selective pressures on the individuals that are parasitized? Cowbird eggs usually look very different from the host's own eggs, so why haven't host species evolved the ability to recognize an intruder egg and remove it from the nest? Indeed, the European common cuckoo (*Cuculus canorus*) is also a nest parasite, but its eggs closely mimic the eggs of its host species, presumably an adaptive response to an improved ability among host birds to discriminate and remove cuckoo eggs (an example of an evolutionary "arms race").

But in some cases eliminating the parasite's eggs can have negative consequences for the host. Researchers have reported observing what they hypothesize to be a kind of "mafia behavior" by cowbirds, in which the female cowbird periodically returns to inspect the

Big Babies Chicks hatched from eggs laid by parasitic cowbirds (*Molothrus ater*) are frequently found in the nests of much smaller species such as the yellow warbler (*Dendroica petechia*). The cowbird chick grows rapidly, exceeding the size of the host parent. The cowbird chick's demand for food is so great that the host's own offspring may be ignored and die of neglect.

nests she has parasitized. If she finds her egg missing, she destroys the nest along with the host's eggs. Female cowbirds have also been observed to destroy the unparasitized nest and eggs of a potential host. Researchers suggest this "farming behavior" may force the owner of the destroyed nest to rebuild and lay a new clutch of eggs—at which time the cowbird can lay her egg in the new nest.

Students of animal behavior seek to understand how behaviors such as nest parasitism evolve, how they develop, and what their underlying mechanisms are. That quest, as in this cowbird example, frequently requires research that includes the environment and interacting species. Behavioral biology is a highly integrative field that incorporates approaches from virtually all the biological subdisciplines. The study of animal behavior can give us insights into our own behavior.

Could cowbird behaviors create selective pressure for host species not to develop egg discrimination behavior?

See answer on p. 1117.

53.1

What Are the Origins of Behavioral Biology?

Humans have studied animal behavior since prehistoric times. Understanding the habits of potential prey, as well as those of their predators, was of great value to hunters. Appreciation of behavioral traits led to the domestication of animal species. Accounts of animal behaviors such as seasonal appearances and disappearances, mating displays, aggression, prey capture, parental care, and communication are found throughout recorded history. Yet the scientific study of animal behavior did not truly get under way until the early 1900s.

Conditioned reflexes are a simple behavioral mechanism

In the late 1800s, the Russian physiologist Ivan Pavlov was studying the neural control of digestive juice secretion when he observed that not only did the dog he was experimenting on salivate when it smelled food, the animal also salivated whenever the technician who routinely fed the dog entered the room—even when no food was present. Following up this observation, Pavlov substituted a sound stimulus for the technician; a metronome ticked while the dog was fed. After several trials, the dog salivated when it heard the metronome, even if no food was offered.

Salivation in response to the sight, smell, or taste of food is a natural reflex response to a stimulus, but salivation in response to a sound was a learned response. The pairing of a sound with the experience of receiving food conditioned the dog's nervous system to generate a response, which Pavlov dubbed the **conditioned reflex** (Figure 53.1). Pavlov received a Nobel prize in 1904 for his work showing that a simple behavior controlled by the nervous system could be modified through experience. This work stimulated much new research because Pavlov had developed an experimental model of learning.

Going beyond the conditioning of autonomic reflexes, the psychologist B. F. Skinner showed that any random action of an animal could become a conditioned response to a stimulus if a reward was temporally associated with the action and the stimulus. A rat, for example, could be conditioned to press a lever in response to a stimulus if it got a reward when it behaved as the experimenter desired. Because the animal was conditioned to perform an *operation* on its environment, this experimental protocol was known as **operant conditioning** and was viewed as another model of learning.

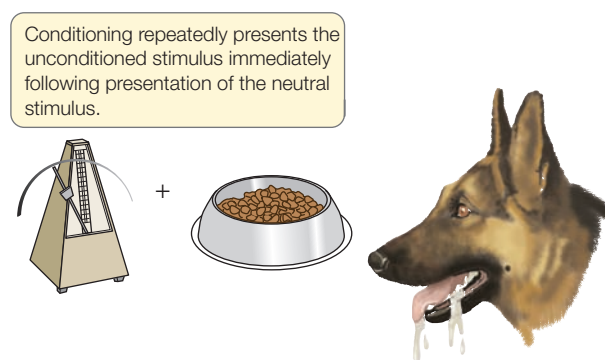

The experimental approaches to behavior initiated by Pavlov and Skinner had powerful effects on the nature of research on animal behavior, and the focus of scientists using their approaches was quite specific:

- They focused on laboratory environments rather than natural environments because in the laboratory, the variables in their experiments could be precisely controlled.
- They focused on only a few species (predominantly the albino rat) as model systems rather than studying diverse species from nature.

(A) Before conditioning

(B) Conditioning

(C) After conditioning

53.1 The Conditioned Reflex Ivan Pavlov discovered that when a normal response is paired with an artificial or neutral stimulus, an animal learns to produce the response even when only the artificial stimulus is presented.

- They focused on questions of learning and memory, largely to the exclusion of other types of behavior (e.g., mating, feeding, communication).

Thus defined, the field of animal behavior research became known as behaviorism and was largely the domain of psychologists.

Ethologists focused on the behavior of animals in their natural environment

An alternative approach to the study of animal behavior arose at the same time as behaviorism, but largely in Europe. Scientists there focused on describing the characteristics of animals in their natural environment, an approach that became known as **ethology** (Greek *ethos*, “character”; *logos*, “study”). In contrast to the behaviorists, the ethologists were interested in a wide variety of species, their evolutionary relationships, and

(A) *Larus marinus*

53.2 Releasing a Fixed Action Pattern (A) In many gull species, chicks instinctively peck at the red dot on the parent's lower bill, a behavior that induces the parent to regurgitate food into the chick's mouth. (B) Tinbergen's work showed that the red dot on the parent's lower bill is the critical component that releases the pecking response.

the ways in which their behaviors were adapted to their environments. The leaders of the ethology movement were Karl von Frisch, who discovered the dance language of honey bees; Konrad Lorenz, who discovered that the strong bond between parent and offspring develops during a "critical period" following birth; and Niko Tinbergen, who studied inborn patterns of behavior commonly known as instincts. These three scientists shared the Nobel Prize in 1973 for "their discoveries concerning organization and elicitation of individual and social behavior patterns."

The ethologists were mainly interested in species-specific or instinctive behaviors that therefore had to have genetic components. Behaviors were thought to be genetically determined if they:

- are performed without learning
- are stereotypic (that is, they are performed the same way each time)
- cannot be modified by learning

The ethologists called such behaviors **fixed action patterns**.

To demonstrate that a behavior was genetically determined, ethologists performed **deprivation experiments** in which an animal was raised in an environment devoid of opportunities to learn its species-specific behavior. An example of a natural deprivation experiment is the web spinning of a spider. The parents of a young spider die before it hatches, and in a seasonal environment it has no model webs to copy when it spins its first web, which requires thousands of stereotyped sequential movements. Yet a young spider creates a perfect, species-specific web the first and every time it spins a web. Thus the information for the web spinning behavior has to be genetically programmed into its nervous system.

Fixed action patterns are usually responses to specific stimuli. The ethologists carefully characterized such stimuli, which they called **releasers**. In general, releasers are simple subsets

of the information available in the environment. For example, Tinbergen studied the begging behavior of gull chicks. Adult gulls have a red dot on their lower bill. When a parent returns to the nest to feed its chicks, the chicks peck on the red dot, which stimulates the parent to regurgitate food (**Figure 53.2A**). Experimenters investigated what stimulated the chicks to peck their parents' bills. Models of gull heads of different shapes and colors were tested (**Figure 53.2B**), as were models of a beak without a head. The results showed that the red dot was necessary for the release of chick pecking behavior. In fact, a pencil with a red eraser elicited a more robust pecking response than an accurate model of a gull head without a red dot.

Ethologists probed the causes of behavior

The ethologists demonstrated the genetic basis for fixed action patterns by interbreeding closely related species. Konrad Lorenz studied the courtship behaviors of different species of dabbling ducks. Some of these species, such as mallards, teals, pintails, and gadwalls, are closely related and can interbreed, but they rarely do so in nature. Each male duck performs a courtship display consisting of a precise series of movements that is typical of his species. A female is not likely to accept him unless the entire display is successfully and correctly completed.

When Lorenz crossbred these duck species, the hybrid offspring expressed some elements of each parent's courtship display, but in novel combinations. Furthermore, Lorenz observed that hybrids sometimes exhibited display elements that were not in the repertoire of either parent species but were seen in other dabbling duck species. Lorenz's interbreeding studies demonstrated that the stereotypic motor patterns of the courtship displays are inherited. The observation that females were not interested in males performing hybrid displays was evidence that sexual selection had shaped these genetically determined behaviors (see Section 21.2).

The ethologists recognized the importance of development and motivation in behavior, and they laid the foundation for the application of modern biological methods to the study of animal behavior. Tinbergen outlined the challenges for investigators as four questions:

- **Causation:** What is the stimulus for the behavior, and how can the relationship between stimulus and behavior be modified by learning?
- **Development:** What experiences are necessary for a behavior to be displayed, and how does the behavior change with age?
- **Function:** How does the behavior affect the animal's chances for survival and reproduction?
- **Evolution:** How does the behavior compare with similar behaviors in related species, and how might it have evolved?

The first two questions refer to the **proximate causes** of behavior: the immediate genetic, physiological, neurological, and developmental mechanisms that determine how an individual is behaving at a particular time. The third and fourth questions refer to the **ultimate causes** of behavior: the evolutionary processes that produced the animal's capacity and tendency to behave in particular ways. In the sections that follow, we will describe many experiments on animal behavior. For each one, ask yourself which of Tinbergen's four questions it addresses and whether it focuses on proximate or ultimate causes of behavior.

RECAP 53.1

Early scientific studies of animal behavior took two approaches. Behaviorists focused on the study of conditioned behavior in a few species of laboratory animals and asked questions about learning. Ethologists studied genetically determined behavior in many species in their natural environments and asked evolutionary questions.

- Describe the difference between conditioned reflexes and operant conditioning. **See p. 1094 and Figure 53.1**
- What is the relationship between a releaser and a fixed action pattern? **See p. 1095 and Figure 53.2**
- Explain the difference between proximate and ultimate causes of behavior and how Tinbergen's questions address these two types of causes. **See p. 1096**

The work of the ethologists left no doubt that behavior can be genetically determined, but how? Genes code for proteins, whereas behaviors are highly complex traits involving sensory input and intricate patterns of control over responses to that input. Is it reasonable to think that a single gene can have a specific effect on a behavior?

53.2 How Do Genes Influence Behavior?

Most behaviors are complex traits that depend on many genes. Nevertheless, evidence from multiple approaches shows that alterations in single genes can result in discrete behavioral phenotypes on which natural selection can operate.

Breeding experiments can produce behavioral phenotypes

Behavioral geneticists identify individuals with unusual behavioral phenotypes and conduct breeding experiments to see if those traits are inherited and to identify the genes involved. The origin of the unusual behavioral phenotypes may come

from diversity in natural populations such as the dabbling ducks that Lorenz crossed; from screening animals subjected to mutagenesis; or from artificial selection experiments.

Examples of single genes involved in complex behavior have come from studies of the circadian rhythms of mutagenized animals. Circadian rhythms, which we will discuss in Section 53.5, are rhythms of behavior and physiology that continue to be expressed under constant conditions with a period that is about (but not exactly) 24 hours—in other words, they reflect an internal clock mechanism. The *per* gene (for period) was discovered in fruit flies, and variants of this gene caused the circadian period to be long, short, or eliminated. *Per* genes are now known to be an important element of the circadian clock in a wide variety of species, including humans. Other genes involved in circadian behavior have been discovered in subsequent mutagenesis and screening experiments.

Very few behaviors can be linked to a single gene, however. Most behaviors are complex traits and are influenced by many genes. A technique called quantitative trait analysis (or QTL, for “quantitative trait loci,” referring to locations on chromosomes) has been developed to identify multiple genes that influence a given trait. QTL analysis requires animals, such as mice, with completely sequenced and well-mapped genomes that have many identifiable genetic markers (i.e., unique DNA sequences). When individuals from two strains of a species that differ with respect to the trait of interest are crossed, the trait can be quantified in the offspring and the offspring can be genotyped to show which of the genetic markers inherited from each parent correlate with the trait of interest in the offspring. Those markers are assumed to be close to the genes that influence the trait. QTL analysis thus points to regions on chromosomes where there are genes that influence the trait of interest.

Knockout experiments can reveal the roles of specific genes

Some modern molecular genetic approaches start with identified genes and eliminate or silence them to see what effects their elimination has on a behavioral phenotype (see Section 18.4). As you might expect, knocking out genes involved in sensory pathways can have pronounced effects on behavior. One example is a gene for a specific olfactory receptor in mice.

As we saw in Section 46.2, mice have two olfactory organs: the nasal olfactory epithelium common to all mammals, and a small organ in the nasal passages called the vomeronasal organ, or VNO (**Figure 53.3**). Catherine Dulac at Harvard University discovered that a large number of pheromone receptors were expressed in that organ. (As described in Section 46.2, pheromones are signaling molecules released into the environment.) Dulac hypothesized that when the receptors in the male's VNO bound to sex pheromones produced by female mice, they stimulated mating behavior. To test this hypothesis, Dulac created a genetically engineered male mouse in which a gene for VNO receptor signaling was knocked out. Contrary to the prediction of the hypothesis, the knockout males in fact did pursue and mate with females placed in their cages. However, they also pursued and tried to mate with *males* placed in their cages. Normally a male mouse reacts aggressively to

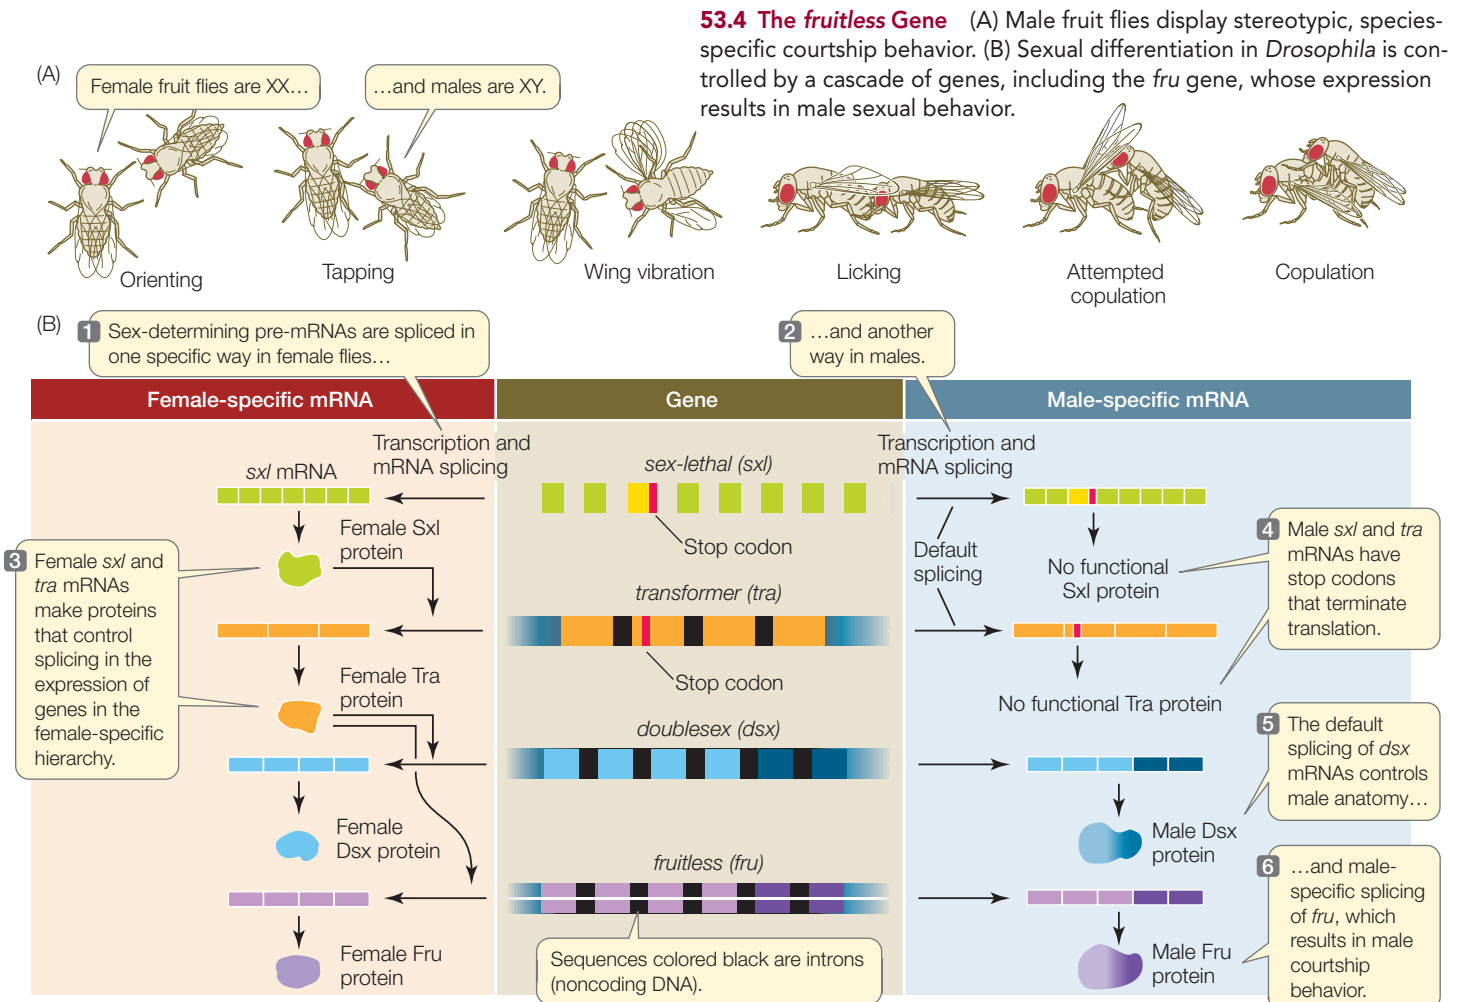

53.3 The Mouse Vomeronasal Organ Identifies Gender (A) The mouse VNO is located adjacent to the nasal passages. It contains pheromone receptors whose input travels to a specific region of the olfactory bulb (the accessory olfactory bulb). (B) In male mice, information from the VNO appears to be crucial in identifying gender and thus a potential sexual partner.

a strange male, but the knockout male could not discriminate between males and females placed in his cage. Thus properly functioning VNO receptors appear to be essential not for sexual attraction, but for gender identification. It is possible to imagine how selection working on this one gene could modify the intensity of male–male aggression and lead to changes in social behavior.

Behaviors are controlled by gene cascades

Male courtship behavior in *Drosophila melanogaster*, the laboratory fruit fly, is stereotypic, species-specific, and requires no learning—a classic fixed action pattern. When a male encounters a potential mate, he follows her, taps her body with his foreleg, extends and vibrates one wing, and licks her genitals (Figure 53.4A). The development of this complex male behavior is under the control of a single gene, called *fruitless* (*fru*), just as the development of male anatomy is under the control of another gene, called *doublesex* (*dsx*). In both males and females, these two genes are part of a gene

expression cascade that results in different *dsx* and *fru* gene products in males and females (Figure 53.4B). The female version of the *Dsx* protein controls the development of female anatomy, and the expression of *fru* in the male nervous system results in the organization of the neural circuitry controlling male sexual behavior.

There are two take-home lessons from this example. First, genes that control aspects of behavior, like other genes, are generally embedded in gene cascades that offer multiple opportunities for simple genetic changes that will alter the phenotype of even complex behaviors. Second, certain genes, such as *dsx* and *fru*, influence a range of other genes that contribute to complex behaviors. Modifications in any one of those genes or its expression can alter behavior. Thus even though no behavior is coded for by a single gene, alterations in single genes can influence behavior in ways that affect an animal's fitness.

RECAP 53.2

Breeding experiments show that behavioral phenotypes can be inherited and modified by natural selection. Although most behaviors are controlled by complex cascades of genes, molecular genetic methods have shown that a single, identifiable gene in the cascade can influence a complex behavior.

- How can knockout experiments reveal genes controlling behavior? See p. 1096 and Figure 53.3
- What is the evidence that the vomeronasal organ in mice is responsible for gender identification? See pp. 1096–1097
- Describe some of the ways a gene can control expression of a complex behavior. See pp. 1097–1098 and Figure 53.4

How can the genetic cascades that underlie complex behaviors be programmed to respond selectively to specific sets of stimuli? How can their expression be limited to appropriate times in an animal's life? The answers to these questions can be found by studying how behaviors develop over the life span.

53.3 How Does Behavior Develop?

The emergence of behavior as an animal develops and matures depends on the development of the nervous system as well as on the growth and maturation of other body systems. A bird cannot fly until its wings grow and its muscles and flight feathers mature. But even with anatomical and physiological competence, specific behaviors may not be expressed. Behaviors that are adaptive at one stage in an animal's life may not be adaptive at other stages. Behaviors typical of juvenile animals, such as begging for food, may disappear and new behavior patterns of a mature individual, such as courtship displays, appear.

Hormones can determine behavioral potential and timing

Hormones can determine the development of a behavioral potential at an early age and the expression of that behavior at a later age. An excellent example of this is sexual behavior in rats (Figure 53.5). Normally, adult male and female rats exhibit different patterns of sexual behavior: females adopt a sexually

(A) Female rats

(B) Male rats

53.5 Hormonal Control of Sexual Behavior Experimental hormone treatments of rats demonstrated that the sex steroids present during early development determine what sexual behavior patterns develop, whereas the sex steroids present in adulthood control the expression of those behavior patterns.

receptive posture, called lordosis, in the presence of males, and males copulate with receptive females. Neither sex, however, expresses these behaviors until the animals have reached adulthood. Experiments in which newborn and adult rats were neutered (to remove the influence of sex steroids naturally produced by their gonads) and artificially treated with hormones led to the following conclusions:

- Development of male sexual behavior requires that the brain of the newborn rat be exposed to testosterone, but development of female sexual behavior does not require exposure to estrogen.
- Testosterone masculinizes the nervous systems of both genetic males and genetic females.
- Exposure to sex steroids in adulthood is necessary for the expression of sexual behavior, but testosterone produces male sexual behavior only in adult rats whose brains were masculinized when they were newborns, and estrogen produces female sexual behavior only in adult rats whose brains were not masculinized when they were newborns.

Thus the sex steroids that are present at birth determine which pattern of behavior develops, and the sex steroids that are present in adulthood determine when that pattern is expressed.

Some behaviors can be acquired only at certain times

Responsiveness to simple releasers is sufficient for certain behaviors such as begging behavior in gull chicks, but more complex information that cannot be genetically programmed is required for other behaviors. An example is parent–offspring recognition. When animals live in close proximity to other individuals, as in a herd or a nesting colony, it is important for parent and offspring to learn each other’s identity soon after birth so they will be able to find each other in a crowded situation. In many such cases, a parent–offspring bond is formed by **imprinting**. What characterizes imprinting is that an animal learns a specific set of stimuli during a limited time called a **critical period**, also known as a **sensitive period**.

Konrad Lorenz demonstrated that young graylag geese (*Anser anser*) imprint on their parents between 12 and 16 hours after hatching. By positioning himself to be present during this critical period, Lorenz succeeded in imprinting goslings on himself. The imprinted goslings followed him around as if he were their parent (**Figure 53.6A**). In a subsequent experiment he had his assistants wear boots with different patterns on them. The goslings imprinted on the boots, and even in a situation that mixed different groups of goslings, they always sorted themselves out by following their “parental” boots.

Imprinting requires only a brief exposure, but its effects are strong and long-lasting. Emperor penguins (*Aptenodytes forsteri*) reproduce during the coldest, darkest time of year in Antarctica. The parents walk up to 150 kilometers inland to form a dense colony, where the female lays her egg. She then walks back to the ocean to feed while her mate incubates the egg. By the time she returns, the chick has hatched. She then takes over its care and feeding, and the father walks back to the ocean to feed. Generally he is away so long that the mother must leave

(A) *Anser anser*

(B) *Aptenodytes forsteri*

53.6 Imprinting Helps Parents and Offspring Recognize Each Other

(A) Greylag geese that imprinted on Konrad Lorenz as hatchlings followed him everywhere he went. (B) Imprinting allows a male emperor penguin to find his own chick among many others.

to find food and to avoid starvation. Thus after being away for weeks, the father must find his chick in a crowded, milling colony of chicks, all calling for their parents (**Figure 53.6B**). Yet he can unerringly locate his own offspring by recognizing its call, which he imprinted on before he left to feed.

The critical or sensitive period for imprinting may be determined by a brief developmental or hormonal state. For example, if a mother goat does not nuzzle and lick her newborn within 10 minutes after its birth, she will not recognize it as her own offspring later. For goats, the sensitive period is associated with peaking levels of the hormone oxytocin in the mother’s circulatory system at the time she gives birth and is sensing the olfactory cues emanating from her newborn kid. A female goat rendered incapable of smelling before giving birth is unable to differentiate between her own kid and other kids after giving birth.

Birdsong learning involves genetics, imprinting, and hormonal timing

Male songbirds use species-specific song to claim and advertise a breeding territory, compete with other males, and declare dominance. They also use song to attract females, which recognize the song of their species even though they do not

53.7 Sensitive Periods for Song Learning (A) Sonogram showing the species-specific song of an adult male white-crowned sparrow (*Zonotrichia leucophrys*). (B) Song of an adult male raised in isolation (never having heard the song as a nestling). (C) Song of an adult male who heard the song as a nestling but was deafened prior to ever singing himself. Marler's experiments showed that the bird must first acquire a song memory by hearing the song as a nestling, and must then be able to hear himself as he attempts to match his singing to that song memory.

sing it. For males of many species, such as the white-crowned sparrow (*Zonotrichia leucophrys*), learning is an essential step in the acquisition of song, but *what* they can learn seems to be influenced by genes, and there is a limited developmental time frame for learning. A hatchling in nature hears his father and other white-crowned sparrows singing. He also hears the songs of many other bird species. But he does not sing until he approaches sexual maturity almost a year later, and when he does, he sings his father's type of song.

Studies of song learning in this species were initiated in the 1960s by Peter Marler at the University of California at Berkeley. Marler incubated eggs of white-crowned sparrows and hand-reared the hatchlings in the laboratory. He was able to expose them to different recorded songs at different times in their development, and discovered that adult male sparrows cannot produce their species-specific song unless they heard it as nestlings in the first 2 months of their lives (**Figure 53.7**). If nestlings hear recordings of white-crowned sparrow song during those first 2 months, they begin to sing (poorly)

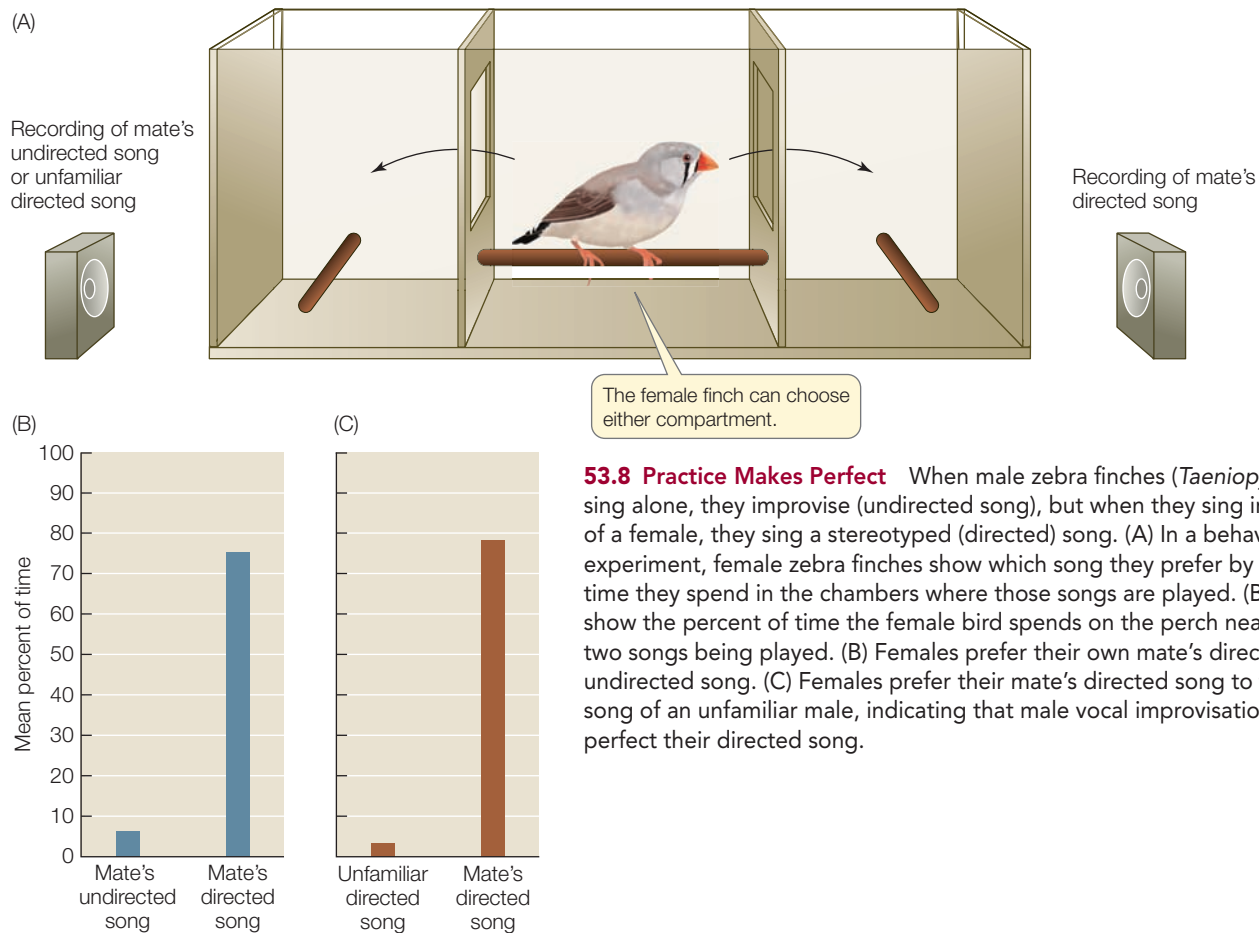

as they approach sexual maturity. Through trial and error, the maturing birds match their singing to their stored song memory, and from then on they sing their species-specific song. To reach this point, the young bird must be able to hear himself sing. If he is deafened before he begins to sing, he will not be able to match his stored song memory correctly. If he is deafened *after* he has sung his correct species-specific song, however, he will continue to sing normally. We say that at this point the behavior pattern is "crystallized." Thus there are two sensitive periods for song learning, the first in the nestling stage when song memory is imprinted, and the second as the bird approaches sexual maturity, when he learns to match that song memory.

In nature, nestling male white-crowned sparrows hear the songs of many species, so why do they learn only the song of their own species? Marler investigated this question in his isolation experiments by playing recordings of other songs to the hatchlings. The young male sparrows did not learn the songs of other species, even if they heard them many times, but hearing songs of their own species just a few times was sufficient for imprinting. Thus although male sparrows must learn their song, they seem to have a genetic predisposition to learn their own song and not the songs of other species. Marler called this phenomenon "an instinct to learn." There is an important reason why male white-crowned sparrows learn only their species-specific song: female white-crowned sparrows also listen to their fathers' songs while they are nestlings, and when they mature, they choose mates that sing like their fathers did.

More recent investigations have revealed additional complexity in white-crowned sparrow song learning capacity. First, it was demonstrated that each population of white-crowns has its own dialect, and that males from one population can learn the dialect of another population. Second, it was observed that in nature, white-crowns are occasionally heard singing the songs of other species. Could Marler's laboratory experiments have missed a critical natural variable?

Luis Baptista, a curator of birds at the California Academy of Sciences, took up the study of white-crowned sparrows to explore the effects of social interactions on song learning. He discovered that when a hand-reared white-crowned sparrow nestling was exposed to the sight and sound of a related species in an adjacent cage while recordings of his own species' song played in the background, the white-crowned sparrow sang the song of the other species when he matured. Thus social experience has a powerful effect on what the young bird can and will learn.

To ask the question of what the adaptive significance of plasticity in the male singing behavior is, it is necessary to take female choice into consideration. Sarah Woolley and Allison Doupe at the University of California, San Francisco have done that with zebra finches (*Taeniopygia guttata*), a species that has become a valuable model system for studying the neurobiology of bird-song. When male zebra finches sing in isolation, their song is variable ("undirected"), almost as if they are improvising. When they sing in the presence of females, however, their song is very stereotyped ("directed"). Experiments by Woolley and Doupe

53.8 Practice Makes Perfect When male zebra finches (*Taeniopygia guttata*) sing alone, they improvise (undirected song), but when they sing in the presence of a female, they sing a stereotyped (directed) song. (A) In a behavioral choice experiment, female zebra finches show which song they prefer by the amount of time they spend in the chambers where those songs are played. (B, C) The graphs show the percent of time the female bird spends on the perch nearest each of the two songs being played. (B) Females prefer their own mate's directed song to his undirected song. (C) Females prefer their mate's directed song to the directed song of an unfamiliar male, indicating that male vocal improvisations may serve to perfect their directed song.

showed that female zebra finches preferred directed song and that the directed song resulted in greater activation of auditory areas in their brains. The strongest effects were seen in mated females hearing the directed song of their mates (**Figure 53.8**). Clearly females are differentially responsive to small variations in the male's song. It appears that the males practice variations in their song but then consolidate the song into a "performance" version that attracts females.

The timing and expression of birdsong are under hormonal control

As we have seen, both male and female songbirds hear their species-specific song as nestlings, but only the males of most species sing as adults, and most do so only in spring. Hormones underlie both the difference in song expression between male and female songbirds and the timing of song expression.

To determine whether the absence of testosterone is the main reason female songbirds don't sing, investigators injected adult female songbirds with testosterone in spring. In response to these injections, females sang their species-specific song just as males did. Apparently females form a memory of their species-specific song when they are nestlings, and have the physical capacity to sing, but under normal circumstances they simply lack the hormonal stimulation.

How does testosterone cause a songbird to sing? A study by Fernando Nottebohm at Rockefeller University revealed that each spring an increase in circulating testosterone levels causes certain parts of the male's brain necessary for learning and developing song to grow larger. Individual neurons in those regions of the brain increase in size and grow longer extensions, and the number of neurons in those regions increases. Thus hormones can control behavior by changing brain structure as well as brain function, both developmentally and in response to environmental cues.

What triggers the release of testosterone in response to the onset of spring? Takashi Yoshimura conducted a DNA microarray analysis of brain samples from another bird species, the Japanese quail (*Coturnix japonica*), which is a model species for avian genetic analyses. Knowing that photoperiod was the environmental cue, he examined the responses of 38,000 genes to determine which genes were activated by changes in day length. Fourteen hours after dawn on the first day of the critical photoperiod that induces singing behavior, genes in the brain that code for thyroid-stimulating hormone were switched on. This hormone acts on the pituitary gland, which in turn regulates the production of other hormones that stimulate the growth of the testes and the production of testosterone (see Figure 43.10).

RECAP 53.3

Hormones can control what behavior patterns are programmed in the brain long before those behaviors are expressed. Learning and expression of behaviors can also be controlled by hormones, and therefore timed for particular stages in the life cycle.

- What hormonal conditions are necessary for the development of adult sexual behavior in male and female rats? See pp. 1098–1099 and Figure 53.5
- What is the adaptive value of imprinting? See p. 1099
- Describe the series of events necessary for a male white-crowned sparrow to sing its species-specific song in spring. See pp. 1100–1101 and Figure 53.7

Complex behaviors are the product of interactions of genetic, physiological, and environmental factors. Many genes are involved in shaping behavior, and therefore there are multiple opportunities for selection to favor behavioral modifications.

WORKING WITH DATA:

Why Put Up with a Parasite?

Original Paper

Hoover, J. P. and S. K. Robinson. 2007. Retaliatory mafia behavior by a parasitic cowbird favors host acceptance of parasitic eggs. *Proceedings of the National Academy of Sciences USA* 104: 4479–4483.

Analyze the Data

A nest or brood parasite lays her eggs in the nest of a different species, who then raises the parasite's chicks at the expense of the host's own reproductive success. Brood parasitism has evolved in several bird species, including cuckoos and cowbirds. Why do the host birds accept this behavior, especially if the parasite's eggs and/or hatchlings are clearly distinct from their own? Why don't the host parents just push the parasite's eggs or offspring out of the nest?

In several cases researchers have observed what they call "mafia behavior," in which the parasitic female returns to the host nest and, if her eggs have been removed, destroys the nest completely. Jeffrey Hoover and Scott Robinson studied the interactions of the brown-headed cowbird (*Molothrus ater*), a North American brood parasite, and one of its common host species, the prothonotary warbler (*Protonotaria citrea*). These experiments placed warbler nests in five treatment categories, two of which protected the warbler nests from any approaching cowbird ("cowbird access denied") and three of which allowed the cowbirds access to the nests (see the table). Hoover and Robinson then tracked the incidence of nest destruction by cowbirds and the average number of warbler offspring fledged per warbler nest in each treatment category, as summarized in the two histograms below.

QUESTION 1

Under which conditions were warblers most successful? Under which conditions were warbler nests most likely to be destroyed?

Questions about how changes in behavior adapt animals to environmental conditions are the province of an evolution-based field called **behavioral ecology**.

53.4 How Does Behavior Evolve?

Animal behaviors are variable within and among species. We saw at the start of this chapter that the behaviors of North American brown-headed cowbirds and European common cuckoos—two groups of avian brood parasites—have taken subtly different evolutionary pathways, and that these differences have resulted in different responses on the part of the host birds these parasites affect.

Along with the forces of intra- and interspecific interactions on evolution, environmental conditions are also highly variable over both time and space. Behavioral ecologists strive to discover the relationships between behavior and environment with the intent of understanding the evolutionary mechanisms underlying behavior.

Treatment	Description
1	Cowbird egg ejected, cowbird access allowed
2	Nonparasitized nest, cowbird access allowed
3	Cowbird egg accepted, cowbird access allowed
4	Cowbird egg ejected, cowbird access denied
5	Nonparasitized nest, cowbird access denied

QUESTION 2

Do these results demonstrate a cost–benefit approach to the evolution of behavior? Explain your answer.

Animals are faced with many choices

Over an animal's lifetime, its behavior is largely a sequence of choices: where and when to move, where to build a nest, what to eat, when to fight and when to flee, with whom to associate, with whom to mate. Making wrong choices reduces fitness. Behavioral ecologists seek to discover what information animals use to make behavioral choices and how that information relates to aspects of the environment that influence their fitness.

Where an animal lives is referred to as its **habitat**. In most cases the habitat provides not only a protected nest site, but also food and access to mates. The environmental cues animals use to select their habitat may be quite simple. For example, seabirds select cliffs or offshore rocks for nesting, and both of those sites offer protection from predators. Animals with very specialized food requirements select habitats where those foods are abundant. The general hypothesis that guides behavioral ecologists is that the cues animals use to select habitats are reliable predictors of conditions suitable for future survival and reproduction.

For many species, the presence of **conspecifics**—other members of the same species—can be a valuable cue. Observing conspecifics can provide animals with information about the quality of a habitat. After all, you can't argue with success. In Europe, collared flycatchers (*Ficedula albicollis*) in the spring breeding season are nosy neighbors, regularly visiting the nests of conspecifics. Researchers hypothesized that this behavior allows the flycatchers to assess the quality of the habitat by seeing how well their neighbors are faring. To test this hypothesis, they created some areas with supersized broods—normally an indication of abundant food—by taking young birds from some nests and adding them to nests in another area. The next year, flycatchers preferentially settled in the areas where broods had been artificially enlarged.

Behaviors have costs and benefits

Behavioral ecologists often use a cost–benefit approach to investigate the relationship between behavior, environment, and fitness. A **cost–benefit approach** assumes that an animal has only a limited amount of time and energy, and therefore cannot afford to engage in behaviors that cost more to perform than they bring it in benefits. A cost–benefit approach provides a framework that behavioral ecologists can use to make observations, construct hypotheses, and design experiments to investigate why behavior patterns evolve as they do.

The benefits of a behavior can be measured in terms of the enhancement in fitness an animal accrues by performing the behavior. The cost of a behavior typically has three components:

- **Energetic cost** is the difference between the energy the animal expends performing the behavior and not performing it.
- **Risk cost** is the increased chance of being injured or killed as a result of performing the behavior.

- **Opportunity cost** is the benefit the animal forgoes by not being able to perform other behaviors during the same time interval.

Territorial behavior carries significant costs

Cost–benefit analysis has been used extensively in the study of **territorial behavior**, which is aggressive behavior that actively denies other animals access to a habitat or resource. Optimal habitats and resources are frequently in short supply, so conspecifics must compete for them. Many animals—usually males—defend all-purpose territories that provide a nest site, food, and access to mates. The territory holder stakes out his boundaries by engaging in aggressive interactions with neighbors, and must then patrol those boundaries constantly and respond to trespassers. These aggressive interactions usually consist of highly stereotypic, species-specific displays such as birdsong. Through territorial behavior, the male obtains the resources he needs for reproductive success, but he also pays a price.

Territorial displays require considerable expenditure of energy, they make a male more vulnerable to predation, and they detract from the time he has for feeding or engaging in parental behavior. Michael Moore and Catherine Marler at Arizona State University performed an experiment to estimate the costs incurred by male Yarrow's spiny lizards (*Sceloporus jarrovi*) when defending a territory. These lizards defend territories that include the home ranges of several females. Their territorial behavior is normally most intense during September and October, when the circulating testosterone levels of the males are high and the females are most receptive to mating. The researchers varied the intensity of the lizards' territorial behavior by implanting testosterone capsules in some males in summer, when they are not normally highly territorial (**Figure 53.9**).

Testosterone-treated males spent more time patrolling their territories, performed more displays, and expended about one-third more energy than control males (an energetic cost). As a result, they had less time to feed (an opportunity cost), captured fewer insects, stored less energy, and had a higher death rate (a risk cost). In summer, when females are not normally receptive, these high costs of vigorous territorial defense outweigh the reproductive benefits of territoriality. Thus natural selection has favored seasonal variation in the level of the hormone controlling territorial behavior in this species.

Go to Animated Tutorial 53.1
The Costs of Defending a Territory
Life10e.com/at53.1

The cost–benefit approach explains the diversity of territorial behaviors seen in different species. Even if a resource is absolutely essential to an animal, if it cannot be defended economically, the animal will not engage in territorial behavior. Food is essential for all animals, but if the food is widely distributed in space or fluctuating in availability, there is no benefit to balance the high costs of trying to defend it. For example,

INVESTIGATINGLIFE

53.9 The Costs of Defending a Territory By using testosterone implants to increase territorial behavior, Michael Moore and Catherine Marler measured the costs to male Yarrow's spiny lizards (*Sceloporus jarrovi*) of defending a territory during the summer, when they do not normally do so.^a

HYPOTHESIS Yarrow's spiny lizards do not defend a territory during summer because the energetic costs of territorial behavior in that season outweigh the benefits.

- Method**
1. During the summer, when female lizards are not sexually receptive, insert testosterone capsules under the skin of some males; leave other males untreated as controls.
 2. Observe the patterns of territorial behavior and the survival rate of the two groups of males.

Results

Testosterone-treated males spent a higher percentage of their time engaged in territorial behaviors than untreated males did.

CONCLUSION For these lizards, the cost of defending territories during summer significantly reduces their survival rate without increasing their reproductive success.

Go to **BioPortal** for discussion and relevant links for all INVESTIGATINGLIFE figures.

^aMarler, C. A. and M. C. Moore. 1988. *Behavioral Ecology and Sociobiology* 23: 21–26.

the open ocean where seabirds feed cannot be defended. But safe nest sites on islands or rocky cliffs are in short supply, and they can be defended. Thus the territories of seabirds may be no larger than the distance the birds can reach while sitting on their nests (Figure 53.10A).

In some cases the resource that is defended is the female herself. Elephant seals spend most of their lives at sea, but females come to land at traditional beach sites to give birth to their pups. Male elephant seals arrive at these sites ahead of time and stake out territories through vigorous fighting (Figure 53.10B). When the females arrive on the beaches, they enter the territories of the males. As long as the male territory holder can fend off challengers, he will be able to mate with all the females using his piece of the beach.

One unusual form of male territorial behavior arises in situations in which neither food, nest sites, nor females are defended. A **lek** is an area where males gather for the purpose of engaging in intense displays of their territorial prowess aimed at impressing females and winning the opportunity to mate. Even though space is not limited, each male defends a small piece of real estate on which he performs a display (Figure 53.10C). Those territories closest to the center of the lek are the prime sites, and males compete intensely for those locations. The females visit into the lek, observe the males, and generally mate with the males holding the prime sites. The benefit of this system to the female is that she is inseminated by a successful competitor, and therefore her offspring will carry the genes that contributed to his success. This is another example of sexual selection (see Section 21.2). The costs of lekking to males are high, as they engage in continuous, intense territorial behavior that precludes eating, drinking, and sleeping until they are displaced. The benefit is the chance to maximize their fitness by mating with many females.

Cost-benefit analysis can be applied to foraging behavior

When an animal forages (searches for food), among the decisions it must make are how much time to spend in each location before giving up and moving on, what resources at each location are actually edible, and which of the different types of potential food should be eaten and which should be left alone. By applying cost-benefit approaches to feeding behavior, scientists have produced a body of knowledge known as **optimal foraging theory**, which helps them identify the fitness value of feeding choices. The primary benefit of foraging is the nutritional value of the food obtained: the energy, minerals, and vitamins it contains (see Section 51.1). The costs of foraging are similar to those of other behaviors: energy expended, time lost from other activities that could enhance fitness, and the risk of increased exposure to predators.

Go to **Animated Tutorial 53.2**
Foraging Behavior
Life10e.com/at53.2

Animals frequently have to make choices among food items that may differ not only in terms of energy content, but also abundance or ease of acquisition and processing. Optimal foraging theory predicts that in such situations, animals will make choices that will maximize the rate at which they obtain energy. The more rapidly a foraging animal satisfies its

(A) *Diomedea melanophris*(B) *Mirounga angustirostris*(C) *Centrocercus urophasianus*

53.10 Animals Defend Territories of Different Sizes (A) The nesting territories of many seabirds consist of only as much space as they can defend without leaving the nest. (B) Male elephant seals fight vigorously to defend areas of beach where females haul out of the water to give birth to their pups. (C) Male greater sage-grouse gather at a lek in Colorado to perform displays aimed at impressing females and winning the opportunity to mate.

energetic requirements, the lower the opportunity costs and risk costs of foraging.

Earl Werner and Donald Hall of Michigan State University performed laboratory experiments with bluegill sunfish (*Lepomis macrochirus*) to test this energy maximization hypothesis. In preparation for their experiments, they measured the energy content of water fleas (*Daphnia*) of different sizes (the different food types), how much time bluegill sunfish (the foragers) needed to capture and eat those different food types, the energy they spent pursuing and capturing the different food types, and the rates at which they encountered the different food types under different food densities. Werner and Hall then stocked experimental environments with different densities and proportions of large, medium, and small water fleas. They made two predictions from the energy maximization hypothesis: first, that in an environment with abundant large water fleas, the fish would ignore smaller water fleas; and second, that in an environment stocked with low densities of all three sizes of water fleas, the fish would eat every water flea they encountered. The proportions of large, medium, and small water fleas eaten by the fish under different conditions were close to those predicted by the hypothesis (Figure 53.11).

The energy maximization hypothesis considers food items in terms of the energy they provide, but animals have nutrient requirements in addition to energy that can play a role in shaping their foraging behavior. Essential minerals, for example, are in short supply in some animals' diets, and those animals may

incur large energetic costs and risks to obtain them (Figure 53.12). Foods may also have medicinal value. Chimpanzees, for example, have been observed eating the pith of the plant *Vernonia amygdalina*. The pith contains small quantities of a secondary metabolite (vernonioside B1) that is toxic to chimps at high concentrations, but at low concentrations can kill their intestinal parasites. Chimps that consume this pith have fewer parasites.

RECAP 53.4

Behavioral ecologists seek to explain relationships between variation in behavior and variation in environmental conditions. They seek to discover what information animals use to make behavioral choices and how that information relates to aspects of the environment that influence their fitness. Cost-benefit analysis has been applied to territorial and foraging behavior.

- What might the presence of conspecifics in a habitat tell an animal about that habitat? [See p. 1103](#)
- Describe three types of territorial behavior and the costs and benefits of each. [See pp. 1103–1104 and Figure 53.9](#)
- How can cost-benefit analysis be applied to a behavior? [See pp. 1104–1105 and Figures 53.9 and 53.11](#)

Whereas behavioral ecologists are interested in understanding how the natural environment influences the fitness value of behavioral choices—the ultimate causes of those behaviors, in Tinbergen's terms—other behavioral biologists focus on the physiological mechanisms and principles that underlie behavior—the proximate causes.

INVESTIGATINGLIFE

53.11 Bluegill Sunfish Are Energy Maximizers Based on energy maximization calculations, Earl Werner and Donald Hall predicted (1) that in an environment with abundant large food items (i.e., the water flea *Daphnia*), bluegill sunfish (*Lepomis macrochirus*) would ignore smaller food items and feed preferentially on larger water fleas;

and (2) that in an environment where all sizes of *Daphnia* were scarce, the fish would eat every one they encountered. Such a strategy is in keeping with the cost–benefit hypothesis of foraging behavior.^a

HYPOTHESIS Bluegill food item selection will match the energy maximization predictions of cost–benefit analysis.

Method

1. Measure the respective energy content of large, medium, and small water fleas (*Daphnia*).
2. Use cost–benefit energy maximization calculations to predict the rate at which bluegill sunfish will consume the different sized water fleas under different levels of food abundance (i.e., density of water fleas).
3. Provide bluegills with *Daphnia* of different sizes in varying proportions (represented by the different colored bars) and at different densities.

4. Note the proportions of small, medium, and large *Daphnia* actually eaten by the fish under the different conditions and compare these proportions to the predictions of energy maximization.

Results

The food choices made by bluegills match the predictions of the energy maximization hypothesis.

CONCLUSION Bluegills select food items in accordance with the predictions of energy maximization calculations.

53.5

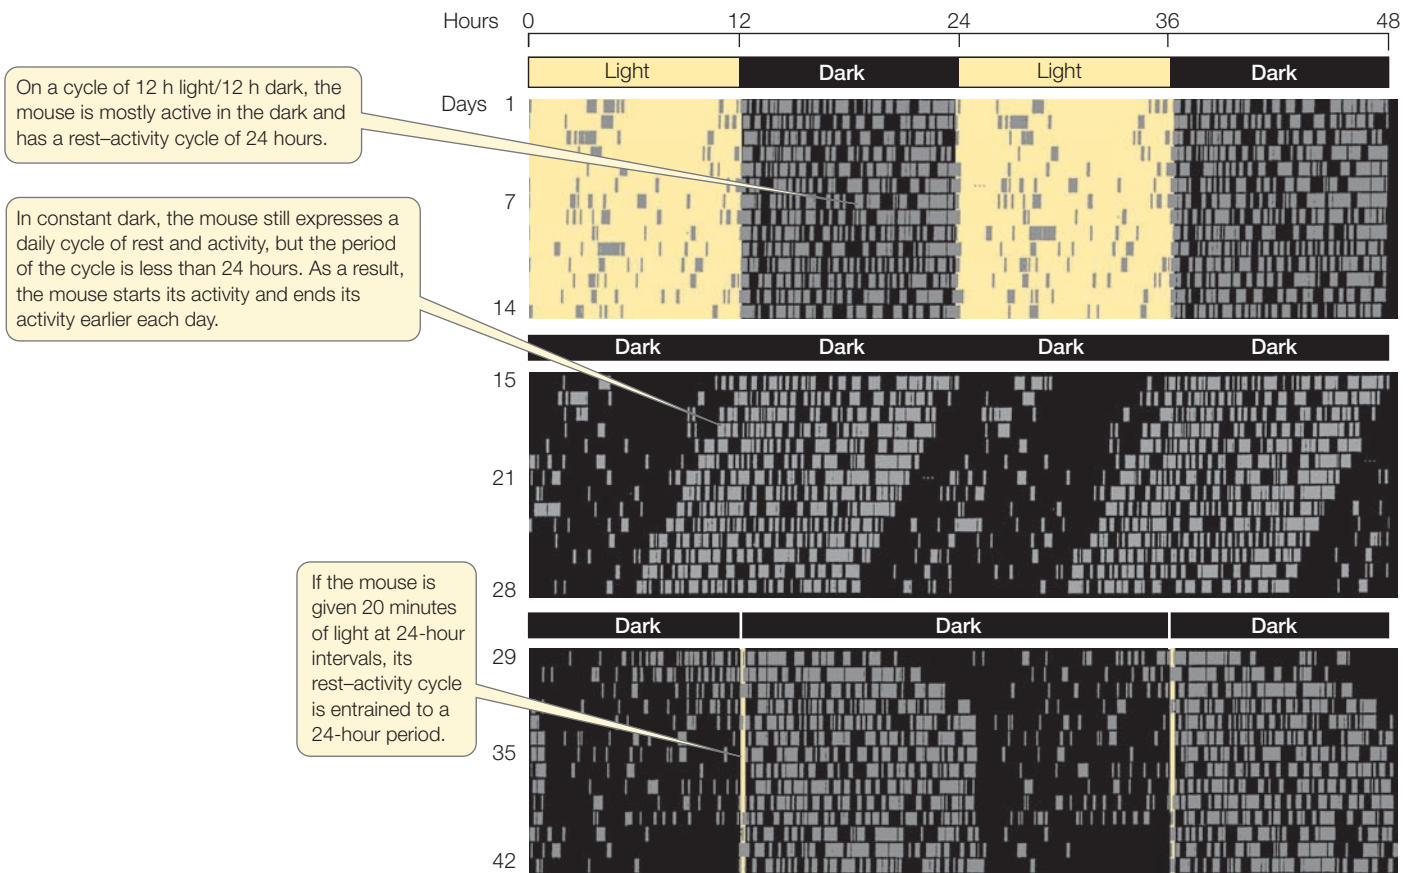

What Physiological Mechanisms Underlie Behavior?

Control of behavior involves the nervous and endocrine systems. Execution of behavior involves the musculoskeletal system as well as other effector mechanisms, such as those that produce secretions, color changes, electrical impulses, sound, and even light. We have already considered many of the physiological systems that are involved in these processes, including hormones, reproductive systems, nervous systems, sensory systems, and feeding mechanisms. The field of behavioral physiology, which encompasses aspects of all of these systems, is enormous, so here we will dig deeper into just three different phenomena studied by behavioral physiologists: the timing of behavior, navigation, and communication.

Biological rhythms coordinate behavior with environmental cycles

Earth turns on its axis once every 24 hours, generating daily cycles of light and dark, temperature, humidity, and tides. In addition, Earth is tilted on its axis, so the light–dark cycle

53.12 Herbivores Seek Out Unusual Sources of Minerals (A) Red-and-green macaws of the Amazon jungle obtain essential minerals by eating dried clay. (B) Pierid butterflies obtain needed salts by drinking secretions from the skin and nostrils of a caiman.

53.13 Circadian Rhythms Are Entrained by Environmental Cues

The activity–rest cycle of a laboratory mouse (a nocturnal animal) responds to the light–dark cycle under which it is kept. The gray bars indicate times when the mouse is running on an activity wheel. Two days of activity are recorded on each horizontal line; the data for each day are plotted twice—once on the *right* half of each line (hours

24–48) and again on the *left* half of the line below it (hours 0–24). This double plotting is merely to make the pattern easier to see.

Circadian Rhythms
Life10e.com/at53.3

changes as Earth revolves around the sun. These daily and seasonal cycles profoundly influence the physiology and behavior of animals. Animals tend to be active either during the day (diurnal) or at night (nocturnal) and have sensory capabilities appropriate to this distinction. Therefore it is adaptive to organize behavior on a cycle that corresponds with the environmental cycle of light and dark. Similarly, a behavior that is adaptive at one time of year (such as midsummer) may not be adaptive at another time (midwinter). Thus it is important for animals to organize their behavior with respect to time of the day or year and to be able to anticipate those times.

CIRCADIAN RHYTHMS Experimental animals kept in constant darkness and at a constant temperature, with food and water available all the time, still demonstrate daily cycles of activities such as locomotor activity, sleeping, eating, drinking, learning, and just about anything else that can be measured. The persistence of these daily cycles in the absence of environmental time cues suggests that animals have an internal clock. Because these daily cycles are not exactly 24 hours long, they are known as **circadian rhythms** (*circa*, “about”; *dies*, “day”).

As described in Section 37.4, any biological rhythm can be viewed as a series of cycles, and the length of one of those cycles is the period of the rhythm. Any point in the cycle is a phase of that cycle. When two rhythms completely match, they are in phase, and if a rhythm is shifted (as in the resetting of a clock), it is phase-advanced or phase-delayed. Because the period of a circadian rhythm is not exactly 24 hours, it must be phase-advanced or phase-delayed each day to remain in phase with the daily cycle of the environment. In other words, the rhythm has to be **entrained** to the cycle of light and dark in the animal’s environment.

An animal kept under constant conditions will not be entrained to the light–dark cycle of the environment, and its circadian clock will run according to its natural period—it will be **free-running**. If the period is less than 24 hours, the animal will begin its activity a little earlier each day (**Figure 53.13**). The period of the free-running circadian rhythm is under genetic control. Different species may have different average periods, and within a species, mutations can lead to different period lengths.

Under natural conditions, environmental time cues, such as the onset of light or dark, entrain the free-running rhythm

to the light–dark cycle of the environment. In the laboratory it is possible to entrain the circadian rhythms of free-running animals with short pulses of light or dark administered every 24 hours (see the bottom panel of Figure 53.13).

In mammals, the master circadian “clock” consists of two clusters of neurons just above the optic chiasm (the area of the brain where the optic nerves come together). These structures are called the **suprachiasmatic nuclei (SCN)**. If they are destroyed, the animal becomes arrhythmic (loses its circadian rhythm) and is just as likely to eat, drink, sleep, or wake at any time of day.

In 1990, a notable study by Martin Ralph and his colleagues, then at the University of Virginia, showed that the SCN is the source of circadian rhythms. When the SCNs of adult hamsters with typical 24-hour rhythms were destroyed, the animals became arrhythmic. After several weeks of this arrhythmic behavior, the researchers transplanted SCN tissue from hamster fetuses bred for an atypical (mutant) short-day rhythmicity into the original hamsters’ brains. The experiment produced two remarkable results (**Figure 53.14**). First, circadian rhythms were restored by the transplanted SCN tissue, demonstrating that the SCN is sufficient to generate circadian rhythms—a unique case of a behavior being restored by a neural transplant. Second, the restored circadian rhythms had the period length of the *donor* strain, demonstrating that the specific phenotype of the behavior was a property of the donor neural tissue, and thus wholly generated by the SCN.

The molecular mechanism of the circadian clock involves negative feedback loops. Although there are a number of genes involved, including the *per* genes discussed in Section 53.2, we can generalize about the mechanism by saying that when certain “clock genes” are expressed in SCN cells, the mRNA enters the cytoplasm, where it is translated. The resulting proteins combine, and the dimer returns to the nucleus as a transcription factor that shuts off the expression of the clock genes. The period of this cycle is about a day. These findings show that it is possible to understand circadian rhythms of behavior at all levels, from the molecular rhythm generators to the environmental stimuli that entrain them to the daily cycle of light and dark.

CIRCAANNUAL RHYTHMS Seasonal changes in the environment present challenges to many species. Most animals reproduce most successfully if they time their reproductive behavior to coincide with the most favorable time of year for the survival of their offspring. Many species require considerable advance preparation for reproduction. Migratory animals must arrive on their breeding grounds at the right time, and animals that have specialized structures used in mating displays, such as the antlers of deer, moose, and caribou, must grow these structures before the breeding season arrives.

For many species, a change in day length—the **photo-period**—is a reliable indicator of seasonal changes to come. For others, however, change in day length is not a reliable seasonal cue. Hibernators, for example, spend long months in dark burrows underground but must be physiologically prepared to

53.14 The Brain Clock Can Be Transplanted In this experiment, the activity rhythm of a wild-type (i.e., genetically typical) hamster was measured; this animal had a circadian period of 24.5 hours (top of bar). After its SCN was removed (lesioned), the hamster became arrhythmic. SCN tissue from a fetal “short-day” hamster (a mutant strain with a 19-hour circadian period) was then transplanted into the region where the lesion was made in the wild-type hamster. The transplanted tissues restored circadian rhythm in the lesioned hamster, but the restored rhythm had the period of the donor animal.

breed almost as soon as they emerge in the spring. A bird overwintering near the equator cannot use changes in photoperiod as a cue to time its migration to its temperate-zone breeding grounds. When held under constant laboratory conditions, such animals show endogenous circannual rhythms that keep track of the time of year. Unlike circadian rhythms, the neural basis for circannual rhythms is unknown.

53.15 Piloting Gray whales (*Eschrichtius robustus*) migrate south in winter from the Bering Sea to the coast of Baja California by piloting, in part by following the western coast of North America.

Animals must find their way around their environment

To locate suitable habitats, find food and mates, and avoid predators and bad weather, an animal needs to be able to find its way around its environment. Within its local habitat, an animal can orient to landmarks. But what if its destination is a considerable distance away?

PILOTING: ORIENTATION BY LANDMARKS Most animals find their way by knowing and remembering the structure of their environment. This form of navigation is called **piloting**. Gray whales, for example, migrate seasonally between the Bering Sea and the coastal lagoons of Mexico (**Figure 53.15**). They find their way in part by following the west coast of North America. Coastlines, mountain chains, rivers, water currents, and wind patterns can all serve as piloting cues for the whales. But some remarkable cases of long-distance orientation and movement cannot be explained by piloting.

HOMING: RETURN TO A SPECIFIC LOCATION The ability to return to a nest site, burrow, or other specific location is called **homing**. Homing can be accomplished by piloting in a known environment, but some animals that travel long distances through unfamiliar territory perform much more sophisticated homing. The ability of pigeons to return to their home loft even after being transported to remote sites is well known. How do they find their way home? Experiments have shown that pigeons use the sun as a compass, but they can still find their way home when the sun is not visible. Other experiments have shown that pigeons equipped with frosted contact lenses can

find their way home, suggesting that visual cues are not essential. Most amazing has been the demonstration that pigeons can detect Earth's magnetic field and orient to it much as a human orients with a compass. Taken together, the studies of homing by pigeons suggest that they can use multiple, redundant sources of directional information and can switch among those sources depending on the circumstances.

Homing Simulation

Life10e.com/at53.4

MIGRATION: NAVIGATION OVER GREAT DISTANCES For as long as humans have inhabited temperate latitudes, they have been aware that entire populations of animals, especially birds, disappear and reappear seasonally. Not until the early nineteenth century, however, were patterns of migration traced by marking individual birds with identification bands around their legs. Only when individuals could be unmistakably identified was it possible to show that the same birds and their offspring returned to the same breeding grounds year after year, and that these same birds could be found during the nonbreeding season at locations hundreds or even thousands of kilometers from their breeding grounds.

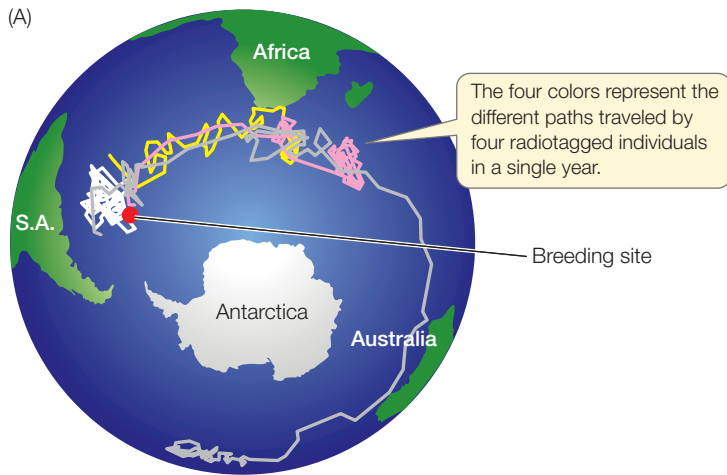

Many homing and migrating species take direct routes to their destinations through environments they have never experienced because they use mechanisms of navigation other than piloting. Humans use two major forms of navigation:

- *Distance–direction navigation* requires knowing in what direction and how far away the destination is. With a compass to determine direction and a means of measuring distance, humans can navigate.
- *Bicoordinate navigation*, also known as true navigation, requires knowing the latitude and longitude (the map coordinates) of both the current position and the destination, as well as a compass to determine direction.

Many non-human animals seem to have a “compass sense” that allows them to use environmental cues to determine direction, and some seem to have a “map sense” that allows them to determine their position.

The behavior of many animals suggests that they are capable of bicoordinate navigation. Gray-headed albatrosses (*Thalassarche chrysostoma*), for example, breed on oceanic islands in the Southern Hemisphere. When a young albatross leaves its parents' nest, it flies widely over the southern oceans for 8 or 9 years (appropriately, the genus name *Thalassarche* is Greek for “first on the sea”). At that time, it reaches reproductive maturity and flies back to the island where it was raised, where it mates and builds a nest (**Figure 53.16**). How can the bird find a tiny island in an enormous ocean after years of wandering? A circadian clock probably gives the albatross information about the time of day, and additional information from the position of the sun might allow it to determine its map coordinates—much as sailors did in the days before global positioning satellites.

The ability to locate a position by calculating the angles between celestial objects such as the sun and stars and the horizon

(B) *Thalassarche chrysostoma*

53.16 Coming Home (A) Gray-headed albatrosses are born on islands in the subantarctic oceans. Young birds roam widely over the southern oceans for 8 or 9 years. (B) Once they reach maturity, the birds return to the island where they were hatched to mate and raise their own young. A courting couple is shown here.

at specific times of day is called celestial navigation. During the day, the sun can serve as a compass if you know what time it is, and animals can use their circadian clocks for that information. This capacity has been demonstrated by “clock-shifting” experiments such as the one shown in **Figure 53.17**. Similar experiments have shown that many animal species can orient by means of a time-compensated solar compass.

Go to Animated Tutorial 53.5
Time-Compensated Solar Compass
Life10e.com/at53.5

Many animals are normally nocturnal; in addition, many diurnal bird species migrate at night and thus cannot use the sun to determine direction. The stars offer two sources of information about direction: moving constellations and a fixed point. The positions of constellations (like that of the sun) change because Earth is rotating. With a star map and a clock, direction can be determined using any constellation. But one point that does not change position during the night is the point directly over the axis on which Earth turns. In the Northern

Hemisphere, the star Polaris—the “North Star”—lies in that region of the sky and reliably indicates north.

Stephen Emlen at Cornell University showed that birds can learn to use the stars for orientation. As the time of year approaches when young birds would normally migrate to their winter range, young captive birds become more active and orient their activity in the direction they would fly. How do they know that direction? If these birds are raised in a planetarium with a natural star pattern, but one that does not rotate, the birds do not learn to orient, and their premigratory activity is random. However, if the planetarium sky rotates, and even if it rotates around a different point than the North Star, the birds orient their premigratory activity as if the fixed point in the sky were north.

Animals use multiple modalities to communicate

As individual animals interact, they exchange information; therefore animal behavior can evolve into systems of information exchange, or **communication**. The behaviors of individuals may become elaborated into communication signals, but only if the transmission of information benefits both the sender and the receiver. To understand why these conditions must be met, consider male courtship displays. These displays will be favored if they increase the male’s probability of mating and passing on his genes, and sexual selection will occur if the display conveys information to a female (the receiver) about his qualities as a potential father for her offspring.

Animals communicate using a variety of sensory modalities that vary in the nature of the signal produced, the specificity of the information conveyed, the speed and persistence of the signal, and its suitability in different environments. Behavioral physiologists interested in communication must take into consideration the sensory and motor characteristics of their study animals, the physics of the communication modalities they use, and the environment in which the communication takes place.

CHEMICAL SIGNALS Because of the diversity of their molecular structures, pheromones can communicate very specific, information-rich messages (see Section 46.2). Pheromones are effective day and night, and they can cover a broad range of transmission distances. Pheromones used in different types of communication vary in their volatility (ease of vaporization) and diffusibility; these chemical properties are functions of the nature and size of the pheromone molecule. Pheromones that act as alarm signals, for example, are highly volatile and diffusible, so their message spreads rapidly but disappears rapidly. Territory-marking and trail-marking pheromones have low volatility and diffusibility and stay effective for a long time, so they can convey directional information. Sex pheromones, such as that of the gypsy moth (see Figure 46.4), are intermediate in these properties, so they can spread a long distance but do not disappear rapidly.

Pheromones are an effective way to exchange species-specific information, and because the recipient must have the proper receptor molecule to detect the pheromone, it is not a signal that is easily intercepted by predators. Pheromonal signals cannot

INVESTIGATINGLIFE

53.17 A Time-Compensated Solar Compass Experiments show that pigeons use the sun to establish directions for navigation and finding food. “Clock-shifting” experiments demonstrate that the

birds’ circadian clocks factor into their ability to judge direction correctly based on the sun’s position.^a

HYPOTHESIS Pigeons determine compass direction from the position of the sun with respect to their internal circadian clocks.

Method

1. Place a pigeon in a circular cage from which it can see the sun and sky, but not the horizon or any other visual cue.
2. Surround the cage with multiple food bins but place food only in the southernmost bin, thus training the bird to look for food in the south. (Rotating the cage but always placing the food in the southernmost bin confirms that the bird is navigating to find south.)

3. Place the trained pigeon in a room with a controlled light cycle for 2 weeks. Turn the lights on at midnight and off at noon to phase-advance its circadian rhythm by 6 hours (i.e., 6 A.M. feels like noon to the bird).
4. Return the pigeon to the circular cage under natural light and observe its food-seeking behavior.

Results

A 6-hour shift in the circadian clock results in a 90-degree error in the pigeon’s orientation.

CONCLUSION Pigeons have the ability to determine direction using the position of the sun as a compass.

^aKramer, G. 1952. *Ibis* 94: 265-285.

be changed rapidly, but they can convey static, complex information. Mammals that mark their territories with pheromones reveal a great deal of information about themselves: species, individual identity, reproductive status, size (indicated by the height of the marking), and how recently the animal has been in the area (indicated by the strength of the scent).

VISUAL SIGNALS Visual signals offer the advantage of rapid delivery of information over considerable distances (depending on the environment and the visual acuity of the receiver); they also convey the exact position of the signaler. Signal content can be enhanced by movements (as in a courtship display) or by different postures. Effective visual signals, however, require sufficient light, and the receiver must be looking at the

signaler. Thus visual communication is not particularly useful at night or in environments that lack light, such as caves and ocean depths. Some species have overcome this constraint with light-emitting mechanisms. Fireflies, for example, use an enzymatic mechanism to create flashes of light. By emitting flashes in species-specific patterns, fireflies advertise for mates at night.

Another drawback of visual signals is that they can be intercepted by other species. There are predatory firefly species, for example, that mimic the flash pattern of females of other species. A male that approaches the mimicking “female” becomes a meal rather than a mate. Thus deception can be part of animal communication systems, just as it is part of human communication.

ACOUSTIC SIGNALS Sound cannot convey complex information as rapidly as visual signals can. But acoustic signals, unlike visual signals, can be used at night and in dark environments. They are not hindered by objects that would interfere with visual signals, so they can be transmitted in complex environments such as forests. They are often better than visual signals at getting the attention of a receiver because the receiver does not have to be looking at the signaler for the message to be received. Sounds are also useful for communicating over long distances. Even though the intensity of a sound decreases with distance from the source, loud sounds can transmit information over much longer distances than visual signals can. The complex songs of humpback whales, when produced at ocean depths of about 1,000 meters, can be heard hundreds of kilometers away, allowing these whales to locate one another across vast expanses of ocean.

The information content of acoustic signals can be increased by varying their frequency, as we can see in the sonograms of the species-specific song of white-crowned sparrows shown in Figure 53.7, and as we practice in our own speech. However, acoustic signals place the signaler at risk for detection by predators. This danger can be minimized by adjustments of frequency and signal structure that decrease the directional information the receiver can extract from the signal. Alarm calls tend to be pure tones (a single frequency) without much temporal structure (starts and stops). It is very difficult to localize such calls. By contrast, territorial calls tend to cover a broad frequency range and have temporal structure. These calls are easy to localize. The frequencies and structures of acoustic signals are also adapted to specific habitats. Different vegetation types, for example, have different sound-absorbing properties: pure tones at lower frequencies carry better in forests, and more complex calls at higher frequencies carry well in open habitats.

MECHANOSENSORY SIGNALS Animals in close contact with one another can communicate by touch. A classic case of mechanosensory communication is the dance of honey bees (*Apis* spp.), first described by Karl von Frisch. Honey bees have a spectacular ability to navigate and can accurately communicate the location of food sources as far away as 10 kilometers. When a forager bee finds food, she returns to the hive and communicates her discovery to her hivemates by performing a vigorous **waggle dance** in the dark hive on the vertical surface of the honeycomb. Other bees follow the dancer and receive her message.

The waggle dance conveys information about both the distance and the direction of the food source. The dancing bee repeatedly traces out a figure-eight pattern as she runs on the honeycomb. She alternates half-circles to the left and right with vigorous wagging of her abdomen in the short, straight run between turns (Figure 53.18). Bees use the sun as their compass, and the angle of the straight run indicates the direction of the food source relative to the position of the sun projected down to the horizon. Even under cloudy conditions, the forager can provide directions to the food source because she can see polarized light. The bee's circadian clock allows the dancer to adjust

53.18 The Honey Bee Waggle Dance (A) A honey bee (*Apis mellifera*) runs straight up on the vertical surface of the honeycomb in the dark hive while wagging her abdomen to tell her hivemates that there is a food source in the direction of the sun. (B) When her waggle runs are at an angle from the vertical, the other bees know that the same angle separates the direction of the food source from the direction of the sun.

Go to Activity 53.1 Honey Bee Dance Communication
[Life10e.com/ac53.1](https://life10e.com/ac53.1)

her dance to take into account the sun's movement during her return flight. The clocks of the recruits enable them to adjust their flight direction to accommodate the sun's movement.

The distance to the food source is communicated by the duration of the waggle portion of the dance. The farther away the food source is, the longer the duration of each waggle run. When food is close to the hive, the waggle portion of the dance becomes so short that it appeared to von Frisch that it was a different dance, which he called a round dance. Recent research, however, has shown that the round and waggle dances are really on a continuum that grades one into the other. Thus the honey bee has one dance language that communicates both the distance and the direction to a food source.

When challenged to prove that the bees were not simply using an odor trail to find the indicated food source, von Frisch responded with a very common sense observation. Bees returning from a new food source fly around barriers such as buildings, but the recruits going out to the food source fly over the barriers in a "beeline," which would be impossible if they were following an odor trail. Careful observation is still one of the best tools for studying behavior.

COMMUNICATION IN MULTIPLE SENSORY MODALITIES Avoiding ambiguity is a high priority in any signaling system. Signal specificity is enhanced if multiple sensory modalities are used. Courtship behavior in fruit flies, for example, involves visual, tactile, chemical, and acoustic signals (see Figure 53.4A). The male fruit fly orients toward the female's line of vision (visual signal) and taps her body with his foreleg (tactile signal). Upon detecting pheromones in her cuticle (chemical signal), the male begins to vibrate one wing, producing a species-specific courtship song (acoustic signal). The male then extends his mouthparts to taste the female's genitalia (chemical and tactile signals); if she is receptive, he initiates copulation. If at any point sensory feedback indicates to either the male or the female that their pairing is inappropriate, the courtship abruptly ends.

RECAP 53.5

Biological rhythms allow an animal to anticipate changes in its environment. In mammals, a circadian clock located in the suprachiasmatic nuclei generates a rhythm that is entrainable by environmental information. The navigational abilities of animals range from simple piloting by landmarks to distance–direction and bicoordinate navigation. Behaviors may evolve into communication signals if the transmission of information benefits both the sender and the receiver.

- What is meant by a free-running rhythm? Describe how it can be entrained to the 24-hour day. **See pp. 1107–1108 and Figure 53.13**
- Explain the difference between piloting, distance–direction navigation, and bicoordinate navigation. **See pp. 1109–1110**
- Explain how a time-compensated solar compass works. **See pp. 1110 and Figure 53.17**
- Describe an advantage and a disadvantage for each of three modalities of communication. **See pp. 1110–1112**

When behaviors involve multiple individuals—or different species, as is the case in the chapter-opening story—we have to consider how natural selection operates on all of the interacting parties, whether they are sending signals or receiving them. This concern becomes particularly relevant in the case of social behaviors.

53.6 How Does Social Behavior Evolve?

The evolution of social behavior became a field of study in its own right in 1975, with the publication of E. O. Wilson's landmark book *Sociobiology*. We begin our consideration of this enormous field with simple interactions that involve a single male and a single female, but already we see diversity. Species differ in their mating systems, which vary from monogamous to promiscuous; in the amount of parental care they give their young; and in the degree to which the male contributes to raising the young. Beyond these relatively simple mating systems, there are associations of larger numbers of reproductive individuals

in **polygynous** mating systems, in which a male has more than one mate, or **polyandrous** mating systems, in which a female has more than one mate. Even more complex interactions exist in which extended families participate in raising young, and finally there are societies such as honey bee colonies in which large numbers of nonreproductive individuals assist a single reproductive individual. Sociobiology seeks to understand the evolution of the diversity of social behaviors by asking how the behaviors contribute to the fitness of *all* of the individuals involved.

Mating systems maximize the fitness of both partners

At the start of Chapter 7 we learned about the mating behavior of two species of voles. Prairie voles (*Microtus ochrogaster*) are monogamous, forming strong pair bonds that can last for life, and both parents participate in rearing the young. In contrast, montane voles (*M. montanus*) are promiscuous: males mate with many females, and the young are raised by the females alone. Behavioral physiologists have explained the proximate mechanisms behind these stark behavioral differences in terms of the release of neurohormones and the distribution of the receptors for those hormones in the brains of the two species. The ultimate question—and the one asked here—is why two such different mating systems evolved in two species that are so closely related.

We begin with the premise that there is an asymmetry in the contributions of male and female animals to their offspring at the time of fertilization. Females produce a limited number of eggs, and each egg is generously stocked with resources. Males produce an almost infinite number of sperm, which contain next to no resources. So the energetic and opportunity costs of reproduction are greater for the female than for the male. In mammals this asymmetry increases throughout gestation as the female bears most of the costs. By the time of birth or hatching, the female's investment in the young is much greater than the male's investment, and the main way for the female to maximize her fitness is to make sure her young are healthy and survive to pass on her genes.

The male has different options for maximizing his fitness. He can simply move on after inseminating the female and seek additional mates as a means of maximizing his reproductive success—as in the case of the meadow vole. Or he can stay with the female he inseminated, protect her, and help care for their young—as in the case of the prairie vole. Which strategy maximizes his fitness depends on a number of factors that are influenced by the species' environment, such as the likelihood that a female and her offspring will survive without a male's help, and a male's likelihood of finding another fertile female. Thus sociobiologists seek to quantify these factors in nature as a means of explaining observed differences in mating systems.

POLYGyny Systems in which a male has more than one mate involve a different asymmetry. In situations in which a male can sequester a group of females from other males, he can increase his fitness by increasing the number of females in his group.

As we saw in Section 53.4, male elephant seals accomplish this by protecting an area of beach where females give birth. Male baboons do so by herding females. Male red-winged blackbirds may acquire more than one mate by defending high-quality nesting territories where females prefer to build their nests. Since sex ratios in all these species are close to 50:50, a large differential in male fitness is established, with some males having high reproductive success while many males have none. Thus selection favors males that are successful in competing with other males to obtain and protect access to many females. In general, bigger, stronger males are the winners, and sexual dimorphism in body size evolves. The elephant seal is an extreme example: males may weigh more than three times as much as females. When species with polygynous mating systems are compared, there is a strong correlation between the number of females a male controls and the degree of sexual dimorphism.

Why do females participate in these polygynous mating systems? Why doesn't a female seek out a nice, kind, noncompetitive male? In some cases she has no choice. If a female elephant seal wants to have her pup on a safe beach, she must enter the territory of a male. If a female red-winged blackbird wants to nest in an optimal territory, she will have to share the attentions of the territory's owner with other females. However, even if the female has a choice of mates, she is likely to maximize her fitness by mating with a male that is strong and dominant enough to control a number of females. Why? If her mate is a dominant male, her male offspring are likely to have their father's traits, become dominant males, and give her more grandchildren. The ultimate result of females selecting males for their prowess and dominance in male–male competition is the lek mating system (see Figure 53.10C), in which the *only* thing a male offers a female is the display of his dominance over other males.

POLYANDRY Mating systems in which one female mates with multiple males are relatively rare, but it is seen in some birds and a few mammal species in which paternal care for the young can have a large effect on fitness. An example of a polyandrous species is the golden lion tamarin (*Leontopithecus rosalia*), a primate native to Brazil's tropical rainforests (Figure 53.19). Tamarins are very small—adults weigh less than 1 kilogram—and so face high predation pressure. Females usually give birth to twins, and thus newborns constitute a higher percentage of maternal weight than is typical of other primates. The young also grow more rapidly than other primates, so nursing costs are high. For all these reasons, young tamarins cared for by their mother alone are unlikely to survive.

What can a male tamarin do to help guarantee his reproductive success? Watching out for predators is one obvious contribution; gathering food for the female and her young is another. Like other primate parents, tamarins carry their young most of the time, but most other primates have single offspring. When tamarin mothers are carrying twins, they spend 92 percent of the time resting, compared with 58 percent of the time when they are not carrying young. Resting is not compatible with foraging and filling the mother's high energy requirements. When a male is present, however, he carries the young about

Leontopithecus rosalia

53.19 Polyandry in a Small Primate The endangered golden lion tamarins of Brazil are small primates whose unique life history has given rise to polyandry in some groups, with males playing a major role in rearing the young.

one-third of the time, so the mother has much more time for foraging and feeding.

If one male tamarin is helpful in protecting and raising young, then two should be even more helpful. Some females can attract a second mate by being sexually receptive to him. Neither male can be sure that any eventual offspring are his, so it is in the best interest of both to help in their rearing. Of the social groups observed in field studies, only 22 percent had one male and one female, whereas 61 percent had multiple males and one female.

Fitness can include more than your own offspring

As humans, we readily understand the concept of extended family—brothers, sisters, aunts, uncles, nieces, nephews. Extended families are a common form of social organization in other species as well, and members of these families may cooperate in territory defense, predator avoidance, foraging, and rearing of young. If behavior is favored when it increases the fitness of the individual performing it, then how can we explain the evolution of social behaviors that do not lead to the performer having more offspring and that may even appear to be **altruistic**—benefiting another individual at a cost to the performer?

An individual's fitness is increased by having offspring because those offspring carry the parent's genes into the next generation. Fitness gained by producing offspring is referred to as **direct fitness**. However, an individual's genes are carried into the next generation by more than his or her own offspring. In diploid organisms, two offspring of the same parents share, on average, 50 percent of the same alleles, and an individual is likely to share 25 percent of its alleles with its siblings' offspring (nieces or nephews). Therefore, by helping parents and other relatives raise their offspring, an individual

Aphelocoma coerulescens**53.20 Helpers at the Nest**

Young Florida scrub-jays often forego reproduction in their first few years of adulthood to help their parents raise their siblings. These young birds help their parents feed the nestlings, defend the territory, and protect the nest from predators.

increases the transmission of those shared alleles to the next generation. **Inclusive fitness** is the individual's direct fitness plus its **indirect fitness**: the reproductive success of the individual's relatives, to the extent that those relatives share the individual's alleles.

The maximization of inclusive fitness is the mechanism driving **kin selection**, selection for behaviors that increase the reproductive success of relatives even when they come at a cost to the performer. One example is "helping at the nest" behavior, which was studied extensively in Florida scrub-jays (*Aphelocoma coerulescens*) by Glen Woolfenden and John Fitzpatrick. Scrub-jay pairs mate for life and establish large territories, which they defend aggressively. The mating pair may be assisted in rearing their young by three to five helpers (**Figure 53.20**). The helpers guard against predators, feed the young, clean the nest, and fly with fledglings. Why are these birds helping others rather than rearing their own young? Through a long-term study, Woolfenden and Fitzpatrick were able to establish a number of important facts:

- The helpers are prior offspring of the mating pair and are usually 1 to 3 years old.
- Young birds that attempt to breed have almost zero reproductive success.
- Mating pairs with helpers have approximately three times the reproductive success of those without helpers.

These results support the conclusion that helper scrub-jays are maximizing their inclusive fitness by helping their parents raise siblings until they are mature enough to have a reasonable probability of successfully raising their own offspring.

The concept of kin selection was formalized by W. D. Hamilton in what has become known as **Hamilton's rule**. He argued that, for an apparent altruistic behavior to be adaptive, the fitness benefit of that act to the recipient times the degree of relatedness between the performer and the recipient has to be greater than the cost to the performer. This relationship was clearly stated years before by the eminent geneticist J. B. S. Haldane, who said during an argument about altruism that he would not be willing to risk his life to save his brother, but for two brothers or eight cousins, he would consider it.

Eusociality is the extreme result of kin selection

Hamilton's rule can be applied to explain **eusociality**: social groups that include nonreproductive members (that is, members who as individuals cannot reproduce). The most obvious examples of eusociality occur among the Hymenoptera, an insect group that includes wasps, bees, and ants. In a honey bee colony, for example, the thousands of individuals in the colony are sterile females.

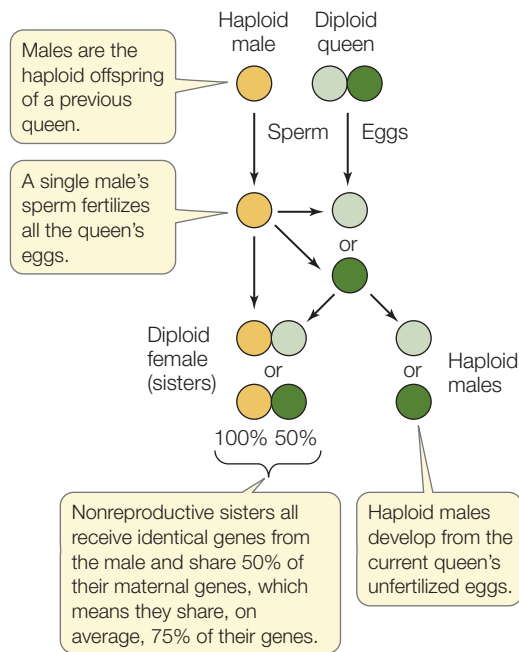

Go to Media Clip 53.1

Social Shrimps

Life10e.com/mc53.1

The key to understanding the evolution of eusociality in hymenopterans is their sex determination mechanism, **haplodiploidy**, in which diploid individuals are female and haploid individuals are male. The queen carries a lifetime supply of sperm obtained during her single mating flight, and she controls whether her eggs are fertilized or not. An unfertilized egg develops into a haploid male; a fertilized egg develops into a diploid female. The queen's daughters share all of their father's genes and, on average, half of their mother's genes. As a result, the sterile female workers in the hive—all sisters—share, on average, 75 percent of their alleles (**Figure 53.21**). Were these females to reproduce, they would share only 50 percent of their alleles with their own female offspring. Thus they potentially increase their inclusive fitness more by raising sisters than by producing and caring for their own offspring.

Eusociality may also arise if it is costly or dangerous to establish new colonies. Nearly all eusocial animals construct elaborate nests or burrow systems within which their offspring are reared. Such a structure represents an enormous investment of resources. Naked mole-rats are eusocial mammals that live in elaborate underground tunnel systems (**Figure 53.22**). A colony includes 70 to 80 individuals but only 1 reproductive female and a few reproductive males. The other colony members are sterile workers that dig and maintain the tunnels, guard against intruders, harvest food (tubers), and use their feces to feed the queen and her offspring. Individuals attempting to found new colonies have a high risk of failing or being captured by predators. When chances of individual reproductive success are practically zero,

53.21 Favoring Sisters over Daughters Female honey bees are diploid and males are haploid. Thus if a female worker bee were to reproduce, she would share approximately 50 percent of her genes with her daughters. However, she shares an average of 75 percent of her genes with her sisters. In terms of inclusive fitness, then, a sister is more valuable than a daughter for this species.

an individual can best maximize its inclusive fitness by staying with and helping maintain the colony.

Group living has benefits and costs

Apart from their direct influences on reproductive success, social systems can contribute to survival in many ways, but they can also involve costs. Thus the cost-benefit approach of behavioral ecology is relevant to understanding the evolution of social behavior.

Heterocephalus glaber

53.22 A Eusocial Mammal Naked mole-rats live in a large colony with one reproductive female and a few reproductive males. Their home is an elaborate tunnel system excavated by the colony over time.

An obvious example of a benefit of group living is improved foraging efficiency. By hunting in packs, African wild dogs (see Figure 59.17) employ cooperative strategies that enable them to bring down larger prey than could a single dog. The larger the pack, the greater the hunting success rate. Once the prey is killed, the presence of conspecifics also reduces the risk that the wild dogs will lose their prey to larger scavengers, such as hyenas.

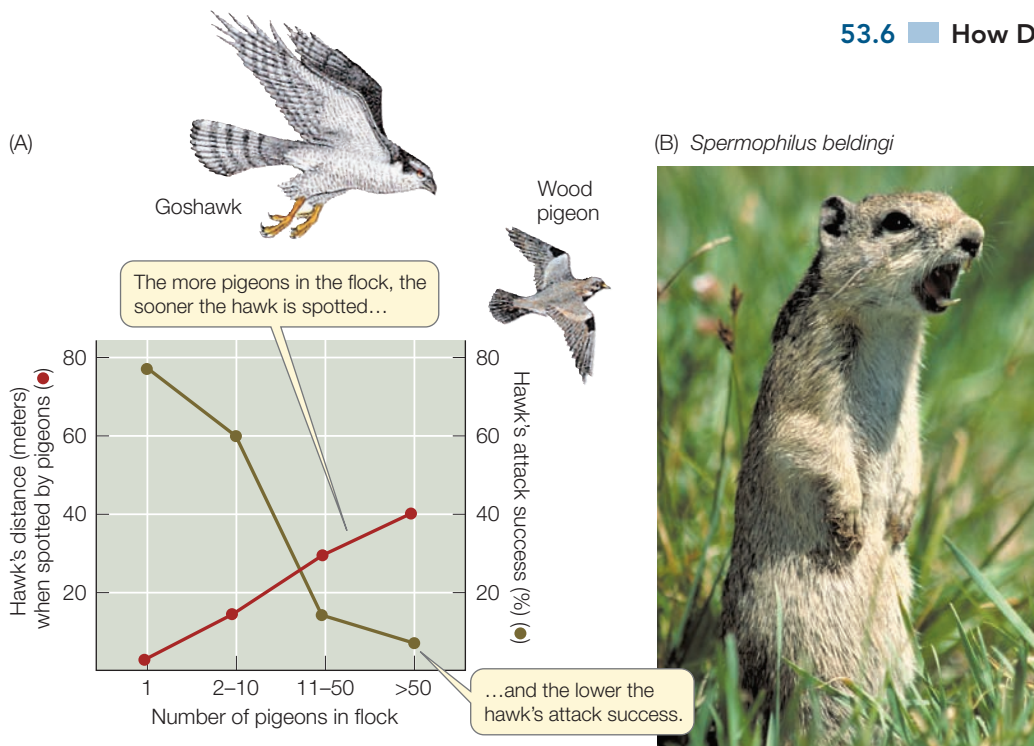

Living in a group can also reduce the risk of individuals becoming prey themselves. Many small birds forage in flocks. To test the hypothesis that flocking provides protection against predators, R. E. Kenward released a trained goshawk (*Accipiter gentilis*) near wild common wood-pigeons (*Columba palumbus*) in England. The hawk was most successful when it attacked solitary pigeons. Its success in capturing a pigeon in a flock decreased as the number of pigeons in the flock increased (Figure 53.23A). The larger the flock, the sooner some individual in the flock spotted the hawk and flew away. This escape behavior stimulated other individuals in the flock to take flight as well.

Alarm calling is another means of reducing predation risk, but the caller incurs a risk cost by calling attention to itself. Belding's ground squirrels live in large colonies in open meadows. When one squirrel announces the presence of a predator with loud, sharp barks, all the nearby squirrels dive into their burrows (Figure 53.23B). Paul Sherman showed that callers double their risk of being preyed on—so why do they do it? Research by Sherman and by others has shown that this altruistic behavior is a product of kin selection. In this polygynous species, males establish large territories in the spring that include the territories of several females, whom they inseminate. The females then drive off the males. Female offspring settle near their mothers, so neighboring females in a colony tend to be sisters, and they defend each other's young. Sherman showed that males are less likely to give alarm calls than females, and that females are more likely to give alarm calls when related individuals are nearby.

Social behavior has many costs as well as benefits. Foraging in a group may reduce the amount of food available to each individual, and the foraging individuals may interfere with one another's foraging activities. Individuals living in groups may face more competition for mates, as well as for food, than solitary individuals would. A large group may actually attract the attention of predators. And living at high population densities can increase the risk of disease transmission. The study of disease transmission in wild animal populations is a relatively new field, but such studies have made it apparent that species living in social groups are more prone to outbreaks of disease than are solitary species.

Can the concepts of sociobiology be applied to humans?

Ever since the publication of E. O. Wilson's *Sociobiology*, applications of the concepts of evolutionary genetics to human behavior have been hugely controversial. The intensity of the debate may stem from impressions that sociobiological approaches resemble previously discredited pseudoscientific movements such as social Darwinism, biological determinism, and eugenics, all of which have been used as rationales

53.23 Group Living Provides Protection from Predators

Animals that live in groups can spread the cost of looking out for predators. (A) The larger the number of common wood-pigeons in a flock, the greater the chances that one of the pigeons will spot a predatory goshawk before it attacks, and the lower the chances that the hawk will capture one of the pigeons. (B) A male Belding's ground squirrel gives an alarm call upon spotting a predator. Although this behavior increases his individual risk of becoming prey, he increases the survival chances of many of his close relatives.

for racism and discrimination. The proponents of sociobiology maintain that theirs is an objective science and that questions of “what is” should not be conflated with questions of “what ought to be.” For example, we can demonstrate the genetic basis of sexual dimorphism in body size and muscle mass in humans, and we can compare this dimorphism with that in other mammals. However, any attempt to use such data as a political or legal defense for polygamy would not be science and should not be confused with science.

The fact that our biochemistry, our cell biology, physiology, and anatomy are shaped by our genes is beyond argument. However, it is also clear that these genetically shaped characteristics are also influenced by factors such as environment, nutrition, social interactions, and culture. Why should it be different for behavior? Studies of identical twins reared apart have produced evidence for inheritance of uncanny similarities in behavioral propensities. Studies of isolated human cultures around the world have also revealed remarkable similarities in social organization. None of these studies, however, would even begin to challenge the dominant role of learning and culture in the shaping of human behavior.

RECAP 53.6

Social behavior can be understood by asking how it contributes to the fitness of the individuals involved. Asymmetry between the sexes in parental investment is a key factor in the evolution of mating systems. According to the theory of kin selection, an individual can increase its fitness by helping related individuals with whom it shares alleles. In extreme cases, kin selection has given rise to eusociality.

- What environmental conditions can lead to monogamy, polygamy, or polyandry? [See pp. 1113–1114](#)
- Explain how an individual can increase its fitness by helping its relatives. [See pp. 1114–1115](#)
- Why is eusociality so common among hymenopterans? [See p. 1115 and Figure 53.21](#)
- What are some of the costs and benefits of group living? [See p. 1116 and Figure 53.23](#)

Knowledge of the behavior of particular species—how they use the environment, how they obtain food, how they organize their activities spatially and temporally—is essential for understanding how species interact in nature. These interactions are one focus of the science of ecology, the subject of Part Ten of this book.

Could cowbird behaviors create selective pressure for host species not to develop egg discrimination behavior?

ANSWER

Results of studies by Jeffrey Hoover and Scott Robinson, some of which were described in the Working with Data exercise on p. 1102, showed that because of nest destruction and other behaviors by cowbirds, hosts that tolerated the cowbird nest parasitism may successfully rear more of their own offspring than those that discriminate against cowbird eggs—a selection pressure on host birds not to discriminate. Of course, when the

experimenters prevented cowbird access to the host nests, the hosts had even greater reproductive success. Thus the host birds were in effect paying “protection money” in the form of nurturing cowbird eggs (and thus reducing but not totally eliminating their own reproductive success), leading the researchers to dub the cowbirds’ actions “mafia behavior.”

53.1 What Are the Origins of Behavioral Biology?

- Ivan Pavlov's discovery of **conditioned reflexes** and B. F. Skinner's research on **operant conditioning** as a model for learning led to an approach called behaviorism that mainly carried out laboratory experiments on rats and a few other animal models. **Review Figure 53.1**
- **Ethology** focuses on both the **proximate causes** of behavior (the immediate cause of the behavior, and how the behavior develops) and on the **ultimate causes** (how the behavior affects the animal's evolutionary fitness).
- A major focus of the ethologists was **fixed action patterns** and their **releasers**. They performed **deprivation experiments** as well as breeding experiments to demonstrate that certain behaviors are genetically determined. **Review Figure 53.2.**

53.2 How Do Genes Influence Behavior?

- Breeding experiments can reveal whether a behavioral phenotype is inherited. Quantitative trait analysis can reveal candidate genes that influence a behavior. Gene knockout experiments can reveal the roles of specific genes underlying a behavioral phenotype. **Review Figure 53.3**
- Most behaviors are complex traits involving many genes that function in cascades and offer many points for a change in a single gene to influence behavior. **Review Figure 53.4**

53.3 How Does Behavior Develop?

- Hormones can determine the pattern of behavior that develops and the timing of its expression. **Review Figure 53.5**
- **Imprinting** is a process by which an animal learns a specific set of stimuli during a limited **critical** or **sensitive period**. That critical period may be determined by hormones.
- The development and expression of song in white-crowned sparrows involves a genetic predisposition to learn the species-specific song, a critical period for imprinting of a song memory, and hormonally controlled timing of song expression. Social interactions may also play a role. **Review Figures 53.7, 53.8**

53.4 How Does Behavior Evolve?

- An animal's behavior involves a series of choices that influence its fitness. To make these choices, animals use environmental cues that are reliable predictors of the potential effects of their choice on their fitness.
- The **cost-benefit approach** can be used to investigate the fitness value of specific behaviors. The cost of a behavior typically has three components: **energetic cost**, **risk cost**, and **opportunity cost**. **Review Figure 53.9, ANIMATED TUTORIAL 53.1**
- According to **optimal foraging theory**, animals should practice feeding behaviors that maximize their energetic gain at the least cost. **Review Figure 53.11, ANIMATED TUTORIAL 53.2**

53.5 What Physiological Mechanisms Underlie Behavior?

- **Circadian rhythms** control the daily cycle of behavior. Without environmental time cues, circadian rhythms free-run with a period that is genetically programmed. They are normally **entrained** to the light-dark cycle by environmental cues. **Review Figure 53.13, ANIMATED TUTORIAL 53.3**
- Forms of navigation used by animals to find their way in the environment include **piloting** (orienting to landmarks), distance-direction navigation, and bicoordinate navigation. Navigation mechanisms include celestial navigation and a time-compensated solar compass. **Review Figures 53.15–53.17, ANIMATED TUTORIALS 53.4, 53.5**
- The behaviors of individuals may become **communication signals** if the transmission of information benefits both the sender and the receiver. **Review Figure 53.18, ACTIVITY 53.1**
- Chemical communication signals (pheromones) can be highly specific and have different time courses. Visual signals can convey complex messages rapidly, but only if the recipient can see the sender. Acoustic signals can travel over long distances, do not require a focused recipient, and can be modified to reveal or conceal directional information. Tactile signals can convey complex messages when animals are in close proximity.

53.6 How Does Social Behavior Evolve?

- **Polygynous** mating systems, in which one male controls and mates with many females, can result in great variation in male reproductive success. **Polyandry**—a female mating with multiple males—can evolve in circumstances in which a male can make a substantial contribution to the survival of his offspring.
- The fitness an individual gains by producing offspring (**direct fitness**) plus the fitness it gains by increasing the reproductive success of relatives with whom it shares alleles (**indirect fitness**) is called **inclusive fitness**. **Kin selection** may favor **altruistic** behavior toward relatives, despite its cost to the performer, if it increases the performer's inclusive fitness.
- As a result of **haplodiploidy**, the sex determination mechanism of hymenopteran insects, nonreproductive female workers (sisters) share more alleles with one another than reproductive females share with their own offspring. **Review Figure 53.21**
- Haplodiploidy has probably facilitated the evolution of **eusocial** behavior in this group through kin selection. Eusociality has also arisen in diploid species in which chances of individual reproductive success are extremely low.
- Group living confers benefits such as greater foraging efficiency and protection from predators, but it also has costs, such as increased competition for food and ease of transmission of diseases.

CHAPTER REVIEW

REMEMBERING

- Which of the following is *not* true of a fixed action pattern?
 - Its expression may depend on hormonal conditions.
 - It is induced by complex, species-specific stimuli.
 - It is highly stereotypic and species-specific.
 - It can be expressed even if the animal has never seen it performed.
 - Its genetic basis can be demonstrated by breeding experiments.
- Which of the following is *not* a component of the cost of performing a behavior?
 - Its energetic cost
 - The risk of being injured
 - Its opportunity cost
 - The risk of being attacked by a predator
 - Its information cost
- Birds that migrate at night
 - inherit a star map.
 - determine direction by knowing the time and the position of a constellation in the rotating night sky.
 - orient to a fixed point in the rotating night sky.
 - imprint on one or more key constellations.
 - determine distance, but not direction, from the stars.
- If a bird is trained to seek food on the western side of a cage open to the sky, and is then placed in a chamber with a controlled light cycle so that its circadian rhythm becomes phase-delayed by 6 hours (i.e., its circadian rhythm is 6 hours behind real time), when it is returned to the open cage at noon in real time, it will seek food in the
 - north.
 - south.
 - east.
 - west.
- Which of the following statements about communication is true?
 - Complex information cannot be conveyed by pheromones.
 - Visual signaling is advantageous in complex environments.
 - Acoustic communication always reveals the location of the signaler.
 - One advantage of pheromones is that the message can persist over time.
 - The dance of honey bees is an example of visual signaling.
- A cost commonly associated with group living is
 - increased risk of predation.
 - interference with foraging.
 - increased exposure to diseases and parasites.
 - increased competition for mates.
 - All of the above
- Altruistic behavior
 - can increase an individual's inclusive fitness.
 - depends on haplodiploid sex determination.
 - is most common among unrelated individuals.
 - always causes a net decrease in the performer's fitness.
 - characterizes a monogamous mating system.
- A group is said to be eusocial if
 - the group's members interact intensively.
 - some members produce many more offspring than others do.
 - a dominance hierarchy exists among group members.
 - young individuals remain in the group to help their parents rear other offspring.
 - the group contains nonreproductive helper individuals.

UNDERSTANDING & APPLYING

- Adult male dogs lift a hind leg when they urinate, whereas young puppies and adult female dogs squat. If a newborn male puppy receives an injection of estrogen, it will never lift its leg to urinate; for the rest of its life, it will always squat. How might this result be explained?
- In most vertebrate species with helpers, the helpers are individuals capable of reproducing, and often breed later. Among eusocial insects, sterile castes have evolved repeatedly. What differences between vertebrates and insects might explain the failure of sterile castes to evolve in vertebrates?
- Studies of birdsong in zebra finches showed that males appear to have "practice" (undirected) songs and "performance" (directed) songs (see Figure 53.8). Field studies show that white-crowned sparrow song has local dialects and that the songs of male birds living only a few kilometers apart are distinguishable. Assuming white-crowned sparrows, like zebra finches, have directed and undirected songs, what could be the adaptive significance of this "practice" versus "performance" behavior?

ANALYZING & EVALUATING

12. Cowbirds are nest parasites, as seen in the opening story of this chapter. What do you think would characterize the acquisition of song in cowbirds? In a given geographical region, cowbirds tend to parasitize the nests of particular bird species. How do you think female cowbirds learn this behavior? How would you test your hypothesis?
13. Some honey bee hives show hygienic behavior: if pupae die in their cells, some workers uncap the cells while other workers remove the carcasses. Some hives do not show this behavior. In a classical behavior genetics study, crosses

were made between hygienic and nonhygienic hives. The results were that about 25% of the resulting hives were hygienic and about 75% were not. Of those that were not, about one-third showed uncapping behavior and about one-third showed carcass removal behavior if cells were uncapped. But there was considerable variability in these data. A recent gene-mapping study (using QTL analysis) revealed seven significant correlations between specific allele frequencies and hygienic behavior. What do the classical data suggest about the genetic basis for hygienic behavior? What do the gene-mapping data suggest? How can you resolve the differences?

54

Ecology and the Distribution of Life

CHAPTER OUTLINE

- 54.1 What Is Ecology?
- 54.2 Why Do Climates Vary Geographically?
- 54.3 How Is Life Distributed in Terrestrial Environments?
- 54.4 How Is Life Distributed in Aquatic Environments?
- 54.5 What Factors Determine the Boundaries of Biogeographic Regions?

FYNBOS IS AN AFRIKAANS WORD derived from the Dutch *fijnbosch*, meaning “fine bush.” It is the name given to an unusual assemblage of plant species found in the western Cape region of South Africa. The Dutch colonists who settled there were probably disappointed by the absence of large, sturdy trees; most of the region’s shrubby vegetation lacks the heft desirable for construction. Most of the plants also have small, slender leaves that are too leathery and tough for any purpose useful to humans.

Fynbos plants may not be useful for construction, but they include some of the world’s most beautiful and popular garden flowers, including geraniums, gladioli, and proteas. Although it covers less than 90,000 square kilometers (smaller than the state of Maine), the fynbos is home to 6,000 endemic species—that is, species found nowhere else in the world.

The fynbos is prone to sweeping wildfires every 15 to 30 years. These fires kill mature plants and trees, which are replaced by vigorous new plants that germinate from seeds buried in the soil or stored in fire-safe cones. If fires are too infrequent, forest trees become established and displace the unique fynbos species. About one-third of these plants depend on ants for dispersal and germination, and their seeds are equipped with a fleshy, lipid-rich structure (an elaiosome). Ants pick a seed up, nibble off the elaiosome, and then store the seed for later consumption, burying it deep enough to avoid injury by fire.

Today more than 1,700 fynbos species are threatened with extinction. For a long time, conservation efforts were stymied by the inability of fynbos seeds to

Fynbos in the Spring This unique vegetation community is restricted to a small region on the western coast of the South African Cape.

germinate in the absence of extensive wildfires. In 1990 two South African botanists discovered that seeds of the rare fynbos plant *Audouinia capitata* germinated in response to smoke from burning wood. Even the “liquid smoke” produced by the food-flavoring industry turned out to be enough to stimulate germination. Investigators in Australia and California then found that the chemicals in smoke stimulate germination in plants in other, entirely different families that also depend on intermittent fires for maintenance.

Fynbos is found only in a small area on the western coast of the South African Cape. Yet this type of vegetation—tough, shrubby, and fire-adapted—is characteristic of many areas around the world that experience hot, dry summers and cool, wet winters. This weather pattern is known as a Mediterranean climate, and similar plant communities are found not only along the Mediterranean coasts of Europe and the Near East but also along the western coasts of Australia, North America, and South America.

What is it about the western edges of continents that promotes tough, shrubby plant communities such as fynbos?

See answer on p. 1146.

54.1 What Is Ecology?

Ecology is the scientific investigation of interactions among organisms and between organisms and their physical environment. Ecology is a relatively new branch of the biological sciences; in fact, it did not even have a formal name until 1866. In 1859 Charles Darwin described the focus of *On the Origin of Species* as being “the coadaptation of organic beings to each other and to their physical conditions of life.” Ernst Haeckel, a German biologist who was profoundly influenced by Darwin, constructed a new word for this new enterprise: “ecology,” from the Greek root *oikos*, “household,” where “household” embraces all of an organism’s environment. As Haeckel put it, “Ecology is the study of all those complex interrelations referred to by Darwin as ‘the conditions of the struggle for existence.’”

Ecology provides explanations of the perceptible, palpable world. Although the *consequences* of enzyme–substrate interactions may be visible, the interactions themselves are not readily visible to the casual observer. In contrast, interactions among organisms, and between organisms and their environment, can often be observed. Analysis of those observations, however, often requires persistence, ingenuity, and additional investigation. That butterflies visit flowers has been observed and admired for centuries; that butterflies perform an essential service to the flowers they visit by transporting pollen is an ecological insight less than 250 years old.

The need for sound science in making decisions about our own species’ interactions with the environment is one key reason for studying ecology. Humans are part of the biotic environment, and our activities have profound effects on a tremendous variety of other organisms, as well as having incalculable effects on abiotic energy flow and nutrient cycling through the physical environment. An understanding of ecology greatly improves our ability to grow food for ourselves reliably and sustainably, to manage pests and diseases safely and effectively, and to deal with natural disasters such as floods and fires. The greater our understanding of ecological interactions, the greater the likelihood that we can accomplish these things without causing a cascade of unanticipated consequences for ourselves and other organisms.

Ecology is not the same as environmentalism

In defining what ecology is, it is important to emphasize what ecology is *not*. “Ecology” is sometimes equated with “environmentalism,” but the two terms are not equivalent. Ecology is a science that generates knowledge about interactions in the natural world; as a field of inquiry, it is not inherently focused on human concerns. **Environmentalism** is the use of ecological knowledge, along with economics, ethics, and many other considerations, to inform both personal decisions and public policy relating to stewardship of natural resources and ecosystems.

Ecologists study biotic and abiotic components of ecosystems

From its beginnings, ecology has encompassed both the living, or **biotic**, components and the physical and chemical,

or **abiotic**, components of ecosystems. The abiotic, physical characteristics of Earth’s atmosphere, for example, determine surface temperatures and precipitation patterns, which in turn limit where organisms can live. The biotic components of an organism’s environment are other organisms, so ecology includes the study of interactions within species and between species. Ecology also encompasses the study of the movement of energy and nutrients through **ecosystems**—the networks of interacting organisms in an area and the physical environment they occupy.

In Haeckel’s time, a main concern of ecology was understanding the distribution and abundance of organisms. That remains true today, but the field has advanced and diversified considerably. A continuous influx of new tools—mathematical models, molecular techniques, and satellite imaging, to name just a few—as well as new or enhanced connections to other fields (particularly the physical sciences) have dramatically changed ecological research. The ultimate goal of ecology, however, remains the same: to provide objective data on the interactions of the different components of the biotic and abiotic environments and, through analysis of the data, to understand these interactions and their various results.

RECAP 54.1

Ecology is the scientific investigation of interactions among organisms and between organisms and their physical environment.

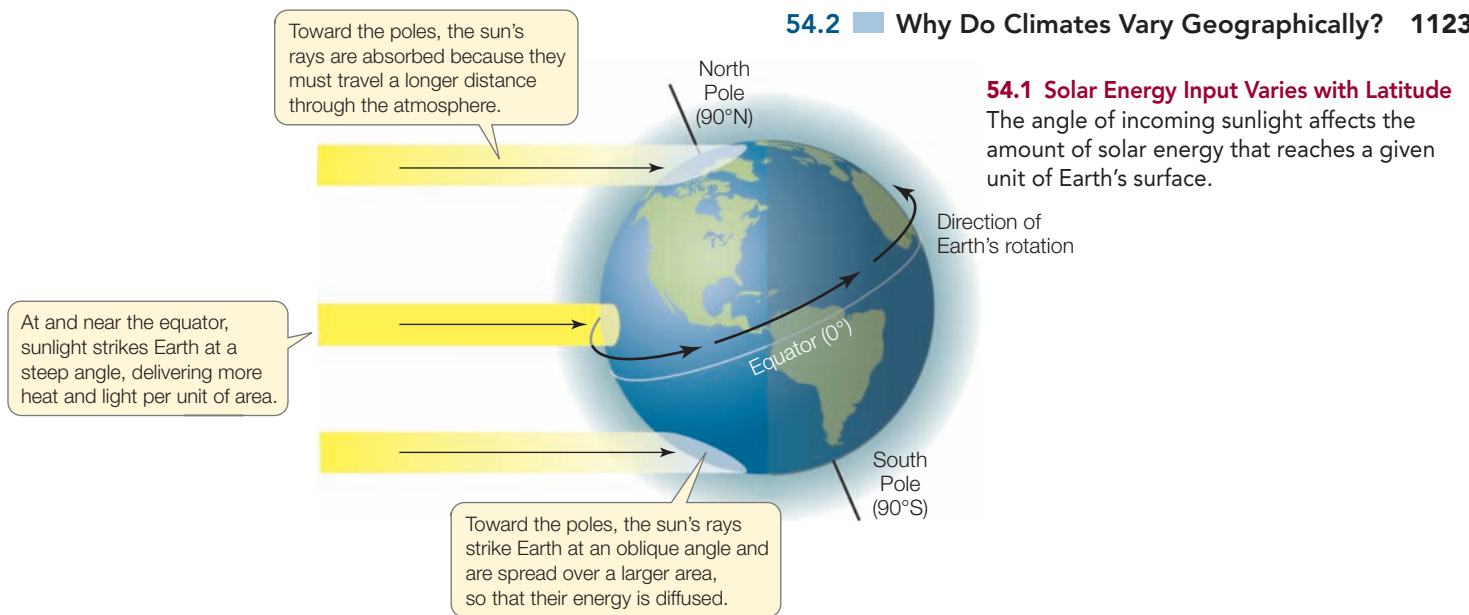

- What are some reasons to consider ecology a useful scientific enterprise? [See p. 1122](#)
- How does ecology differ from environmentalism? [See p. 1122](#)

We will begin our study of ecology as the discipline began in Haeckel’s time, focusing on factors that determine the distribution and abundance of organisms. First we will look at the physical forces that result in climate variation.

54.2 Why Do Climates Vary Geographically?

The terms “weather” and “climate” both refer to atmospheric conditions—temperature, humidity, precipitation, and wind direction and velocity—but they refer to different time scales.

Weather is the short-term state of atmospheric conditions at a particular place and time, whereas **climate** refers to the average atmospheric conditions, and the extent of their variation, at a particular place over a longer time. In other words, climate is what you expect; weather is what you get. The responses of organisms to weather are usually short-term—seeking shelter from a sudden rainstorm, for example, or shivering to keep warm when the temperature drops. Responses to climate, on the other hand, tend to be evolutionary adaptations that arise within populations over time and affect physiology, morphology, and behavior. These adaptations are among the forces driving speciation. If organisms cannot adapt to the climate of a particular place, they will not be found there.

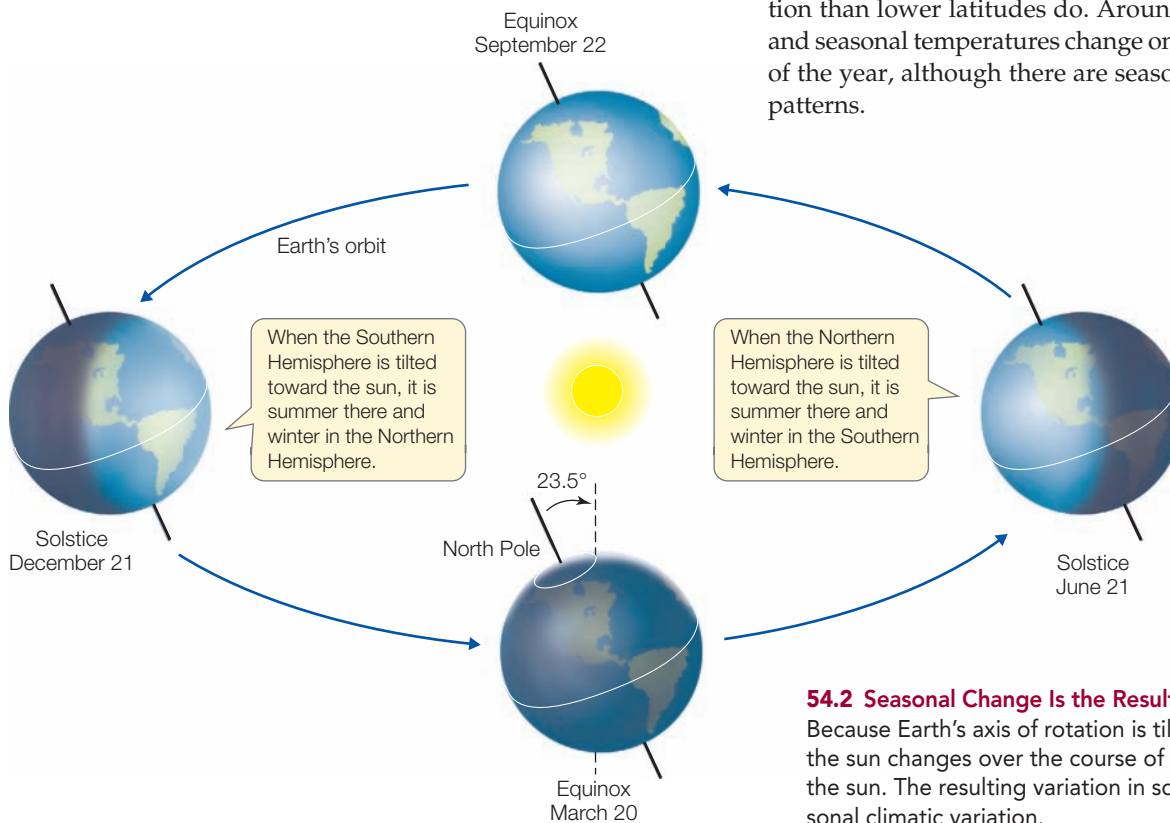

Solar radiation varies over Earth's surface

Solar energy input determines the air's temperature and is the major determinant of climate. The intensity of solar radiation varies over the course of a year and from place to place due to the shape of Earth, its orbit around the sun, and the tilt of its axis. The amount of solar energy reaching a given point on Earth's surface depends primarily on the angle of the sun's rays. At high latitudes (i.e., areas toward the North and South poles), sunlight strikes Earth's surface at an angle, so the incoming solar energy is distributed over a larger area (and thus is less intense) than at the equator, where sunlight strikes the surface perpendicularly (Figure 54.1). Moreover, when coming in at an angle, the sun's

radiation must pass through more of Earth's atmosphere, so more of its energy is absorbed or reflected before reaching the surface. Because of this difference in solar energy input, air at the poles is colder than air at the equator. The average air temperature over the course of a year decreases about 0.76°C for every degree of latitude (about 110 km) at sea level. Air temperatures also decrease with elevation, so temperatures at sea level are warmer than temperatures on mountaintops at the same latitude.

Because Earth's axis is tilted at an angle of 23.5 degrees, the amount of sunlight a particular region of Earth receives varies over the course of a year as Earth orbits the sun (Figure 54.2). This tilt causes seasonal variation in temperature and day length. Higher latitudes experience greater seasonal variation than lower latitudes do. Around the equator, day length and seasonal temperatures change only slightly over the course of the year, although there are seasonal shifts in precipitation patterns.

54.2 Seasonal Change Is the Result of the Tilt of Earth's Axis

Because Earth's axis of rotation is tilted, orientation relative to the sun changes over the course of a year as the planet orbits the sun. The resulting variation in solar radiation creates seasonal climatic variation.

54.3 Air Circulation in Earth's Atmosphere

(A) Solar energy drives patterns of atmospheric circulation. (B) Those patterns, in turn, influence air temperatures worldwide.

Solar energy input determines atmospheric circulation patterns

Air in the region surrounding the equator receives the greatest input of solar energy. When a parcel of air is warmed, it expands, becomes less dense, and rises. As it rises, however, it cools. Cool air cannot hold as much water vapor as warm air, so the expanding, cooling air releases moisture in the form of precipitation. Thus as the sun warms air in the tropics, that air rises into the atmosphere, cools, and releases large amounts of rainfall. As it rises, it is replaced by surface air flowing in from the north and south (Figure 54.3A).

High in the atmosphere, the tropical air is pushed to the north and south as newly warmed air rises to replace it. As it reaches latitudes around 30°N and 30°S, it cools and sinks. This cool, dry air, which lost its moisture as it rose over the equator, now *takes up* moisture from the ground rather than releasing it. Earth's great deserts—including the Sahara of Africa, the Gobi of China, and the deserts of Australia and the American Southwest—are located at these latitudes.

While some of the descending air flows back toward the equator, some of it flows toward the poles, setting up further cyclic movements of air. At about 60° latitude, air rises again. At the poles, where there is little solar energy input, cold, dry air descends (Figure 54.3B). These cyclic movements of air masses are largely responsible for determining air temperatures and precipitation patterns across Earth's surface.

Atmospheric circulation and Earth's rotation result in prevailing winds

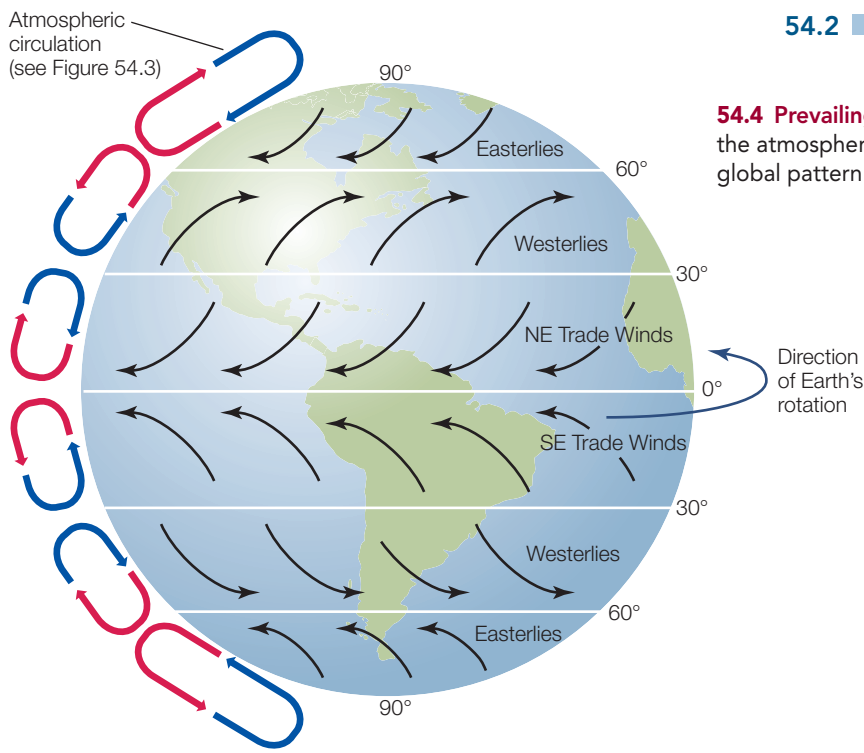

The velocity of Earth's rotation around its axis is fastest at the equator, where Earth's diameter is greatest, and slowest close to the poles. An air mass that is not moving either to the north or the south has the same rotational velocity as Earth does at the same latitude. However, as an air mass moves toward the

equator (driven by the circulation patterns described above and in Figure 54.3), its rotational movement becomes slower than that of the planet beneath it and it is deflected to the west. Conversely, the rotational movement of an air mass moving toward either pole is faster than that of the surface beneath it and is deflected to the east. This interaction of Earth's rotation and north-south air mass movement sets up a pattern of circulating surface air referred to as the **prevailing winds** (Figure 54.4). Prevailing winds blow from east to west in the tropics (the **trade winds**); from west to east in mid-latitudes (the **westerlies**); and from east to west again above 60°N or 60°S latitude (the **easterlies**).

Prevailing winds drive ocean currents

Wind moves the water it blows over by means of frictional drag. Thus global air circulation patterns drive the circulation patterns of surface ocean waters, known as **currents**. The trade winds, for example, cause currents to converge at the equator and move westward until they encounter a continental land mass. At that point, the strong Equatorial Countercurrent brings some of the water back eastward. The remaining water divides, some moving northward and some southward along continental shores (Figure 54.5). These patterns of water movement set up rotating circulation patterns called **gyres** (Greek *gyros*, "spiral"). These great circular currents rotate clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere.

Because the ocean currents transport heat, they have a tremendous effect on Earth's climates. The poleward movement of warm water from the tropics transfers large amounts of heat to high latitudes. The Gulf Stream, for example, carries warm water from the tropical Atlantic Ocean (including the Gulf of Mexico) north across the Atlantic to northern Europe, making the European climate considerably milder than that of corresponding latitudes in North America. Similarly, currents flowing toward the equator from high latitudes bring cool, wet winters to some western coastal regions that are otherwise warm and dry.

Organisms adapt to climatic challenges

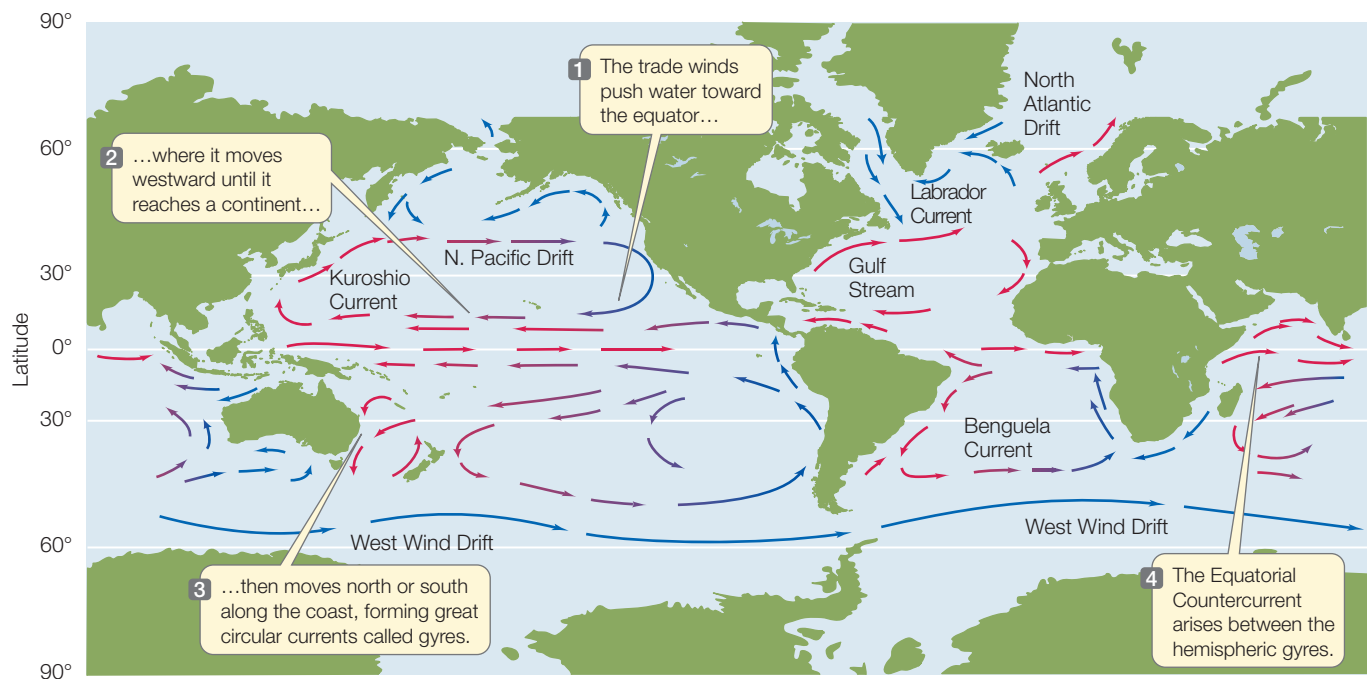

The patterns we have just described give rise to a mosaic of climatic conditions across Earth. The climatic conditions in a region—especially temperature and precipitation—act as selective agents on the organisms that live there. As a consequence, many organisms display adaptations to climatic conditions, which can involve physiological, morphological, or behavioral specializations.

54.4 Prevailing Winds The speed of Earth's rotation combines with the atmospheric circulation of air masses (see Figure 54.3) to create a global pattern of prevailing surface winds across the planet.

Metabolic specializations help many organisms cope with an environment that periodically becomes too hot, too cold, too dry, or short of food. Organisms that must deal with extremely low temperatures, for example, are capable of surviving by a variety of strategies, chief among which is producing antifreezes. Microbes, sponges, Arctic fishes, and many temperate-zone insects are among the organisms that produce antifreezes to lower the freezing point of their cell contents or body fluids (see Section 40.3). One of only two flowering plant species native to Antarctica, the freeze-tolerant hairgrass (*Deschampsia antarctica*), survives by producing proteins that inhibit the formation of damaging large ice crystals. In Alaska the wood frog (*Rana sylvatica*), the only amphibian found north of the Arctic Circle, can survive temperatures of -6°C for more than a month with up to 65 percent of its body fluid frozen solid (Figure

54.6). The frog avoids damage to its cells by allowing fluids to freeze in extracellular spaces.

Adaptation to climatic conditions is often reflected in differences in morphology. For example, some endotherms living in cold climates have proportionally rounder shapes and shorter appendages than their relatives adapted to warmer climates, which gives them a smaller surface area relative to their volume and allows them to conserve heat more easily (see Figure 40.18).

54.5 Oceanic Circulation The surface currents of the ocean are driven primarily by the prevailing winds shown in Figure 54.4.

Rana sylvatica

54.6 An Evolutionary Adaptation to Climate Wood frogs survive frigid Alaskan winters by allowing up to 65 percent of their body fluids to freeze.

Behavioral mechanisms for temperature regulation often complement physiological and morphological adaptations, particularly among ectotherms. An important behavioral adaptation to changing climatic conditions is changing one's location to find a more suitable microclimate. A **microclimate** is a subset of climatic conditions in a small specific area that generally differ from those in the environment at large. For example, some desert lizards maintain their body temperature by spending time in an underground burrow at night (see Figure 40.11). While surface temperatures may fluctuate wildly, the microclimate of the burrow is buffered against such changes.

In addition to such localized movements, long-distance movements can be key adaptations to climatic challenges. Many organisms seek new places to live when local conditions deteriorate. If repeated seasonal changes alter an environment in predictable ways, organisms may evolve life cycles that appear to anticipate those changes. Migration, one response to such cyclic environmental changes, was discussed in Section 53.5.

RECAP 54.2

Latitudinal differences in solar energy input create patterns of atmospheric circulation, which in turn drive oceanic circulation. These air and oceanic circulation patterns determine Earth's climates.

- How does latitudinal variation in solar energy input drive global air circulation patterns? **See p. 1124 and Figure 54.3**
- How do global air circulation patterns drive ocean currents? **See pp. 1124–1125 and Figure 54.5**

The tremendous variation in Earth's climates has given rise to many different environments, all home to assemblages of organisms that are adapted to the local abiotic conditions. Ecologists have found it useful to classify and name these environments based on their ecological similarities.

54.3

How Is Life Distributed in Terrestrial Environments?

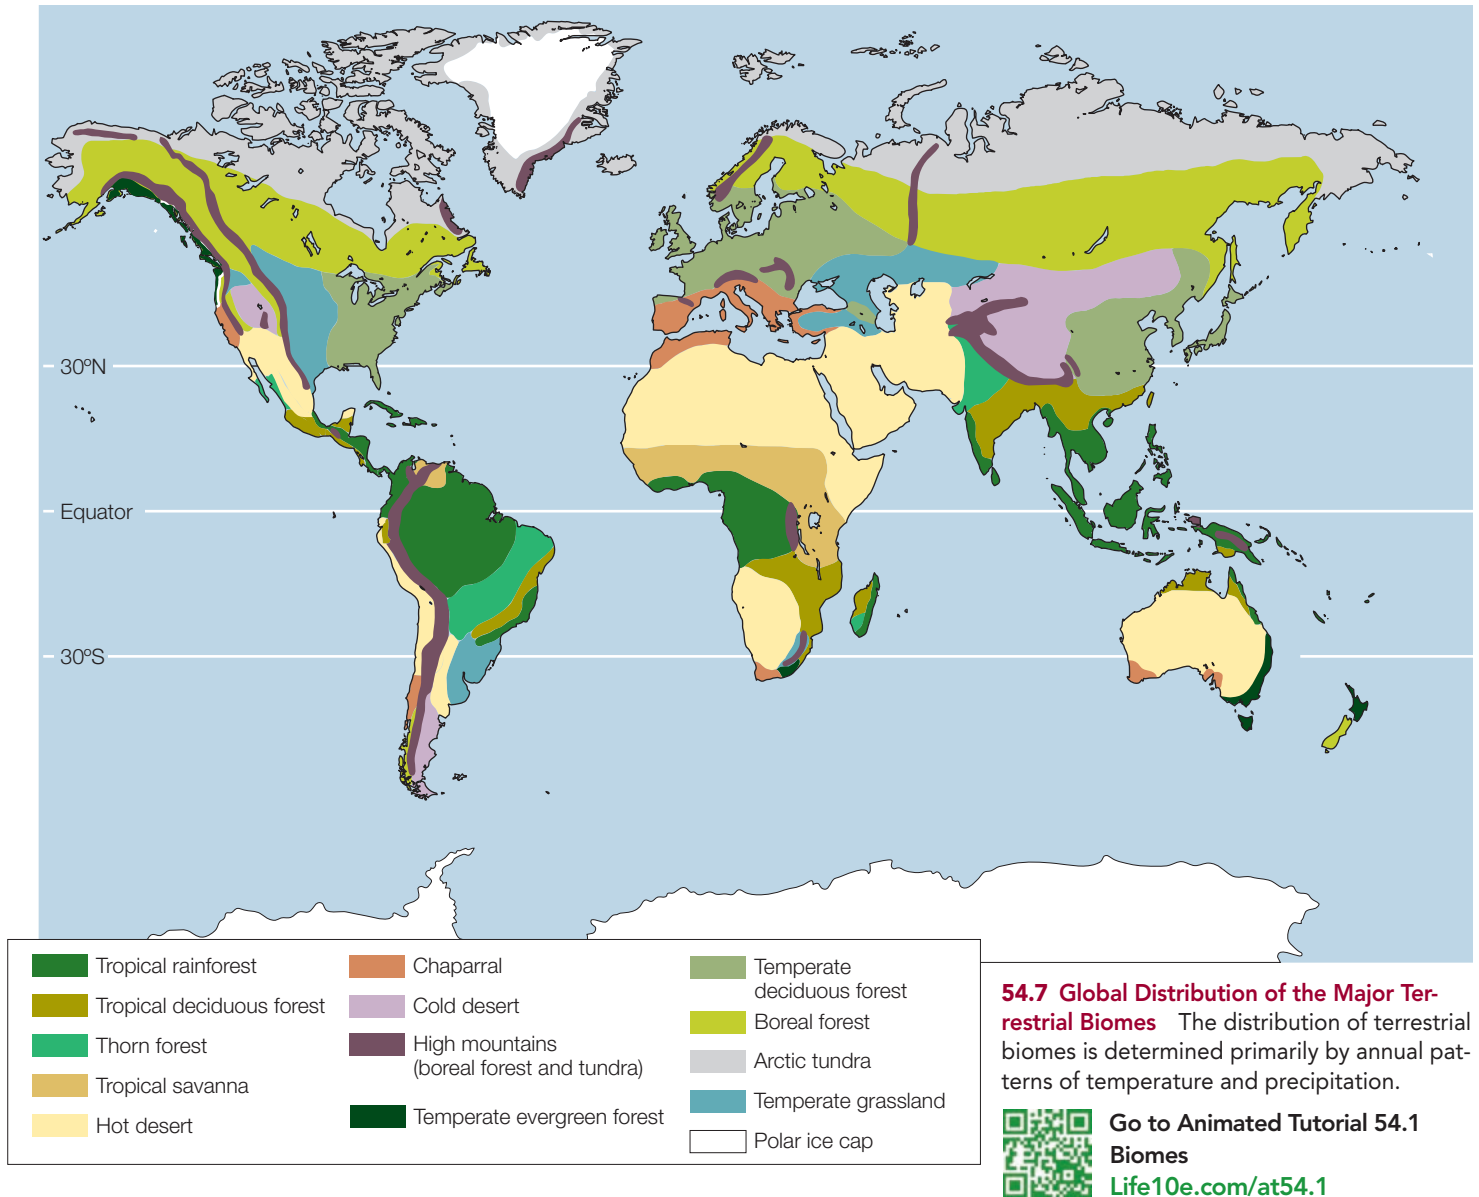

A **biome** is an environment that is shaped by its climatic and geographic attributes and characterized by ecologically similar organisms. Ecologists classify terrestrial biomes principally by their dominant plants. By providing three-dimensional structure and by modifying physical conditions near the ground, the dominant plants of a terrestrial environment strongly influence the existence of the other organisms living there.

The distribution of biomes is determined largely by annual patterns of temperature and precipitation. The same biome may be found in several widely separated places, depending in large part on the presence of suitable climatic conditions (**Figure 54.7**). Different assemblages of species may be found in geographically separate regions, but due to convergent evolution in response to similar selective forces (see Section 22.1), organisms in the same biome are likely to share many physiological, morphological, and behavioral adaptations. The shrubby stature and tough leaves of fynbos vegetation described at the opening of this chapter, for example, are features shared by the dominant plants of other regions that have a Mediterranean climate.

In some biomes, such as temperate deciduous forest, precipitation is relatively constant throughout the year, but temperature varies strikingly between summer and winter. In other biomes, both temperature and precipitation change seasonally. In the tropics, seasonal temperature fluctuations are small and annual cycles are dominated by wet and dry seasons. Tropical biome types are determined primarily by the length of the dry season.

Other abiotic factors—particularly soil characteristics and wildfires—also influence the structure and life cycles of the dominant vegetation in an area and, consequently, the ecological attributes of the other organisms living there. For example, Australian desert soils are extremely nutrient-poor, and plants there have difficulty growing new foliage. Such plants often protect their leaves against consumers by producing large quantities of chemicals that reduce the leaves' digestibility. Since these leaves are not eaten, they senesce and drop to the ground, providing an abundance of highly flammable litter that feeds intense periodic fires that sweep across the landscape. As a result, succulent plants—which are easily killed by fire—are not found in Australia, although they are common in deserts on other continents.

Sometimes biomes occur in close geographic proximity to one another but differ because certain geological features alter local temperature and precipitation patterns. Major topographic features such as mountains or large lakes have regional effects on temperature and precipitation. When prevailing winds bring air masses into contact with a mountain range, for example, the air must rise to pass over the mountains, expanding and cooling as it does so. Thus clouds frequently form on the windward side of a mountain range (the side facing into the winds) and release moisture there as rain or snow. On the leeward side (that is, opposite from the direction of the winds), the now-dry air descends, warms, and once again picks up moisture. This pattern often results in a dry area called a

rain shadow on the leeward side of the mountain range (**Figure 54.8**). The Atacama Desert, on the leeward side of the Chilean Coast Range, is one such area.

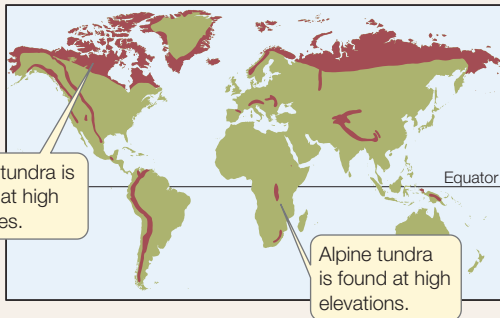

The descriptions of biomes presented here are very general and fall far short of encompassing the variation that can be found in each biome. Moreover, the boundaries ecologists draw between biomes tend to be arbitrary. Although sometimes an abrupt change is apparent in a landscape, more often one biome gradually merges into another. Despite these uncertainties, recognizing the major biomes of the world is useful because these environments share certain ecological attributes irrespective of their locations.

54.8 Rain Shadow Mean annual precipitation tends to be lower on the leeward side of a mountain range than on the windward side.

TUNDRA

Alpine tundra: Giant groundsel (*Dendrosenecio keniensis*) on the slopes of Mt. Kilimanjaro, Tanzania

Arctic tundra: Caribou (*Rangifer tarandus*) in Denali National Park, Alaska

Community composition

Dominant plants

Perennial herbs and small shrubs

Species richness

Plants: Low; higher in tropical alpine

Animals: Low; many birds migrate in for summer; a few species of insects abundant in summer

Soil biota

Few species

The feathery feet and white plumage of the willow ptarmigan (*Lagopus lagopus*) are adaptations to the snows of the Arctic tundra in Manitoba.

Tundra is found at high latitudes and high elevations

The tundra biome is characterized by low temperatures and a short growing season. These conditions prevail not only at the high latitudes of the Arctic but also at high elevations in mountains at all latitudes. In Arctic tundra, the vegetation consists of low-growing perennial plants and is underlain by permafrost—soil permeated with permanently frozen water. The top few centimeters of the soil thaw during the short summers, when the sun may be above the horizon 24 hours a day. Thus even though there is little precipitation near the poles, the soil

in lowland Arctic tundra is wet because water cannot drain through the permafrost.

Tundra found at high elevations outside polar regions is called alpine tundra. Tropical alpine tundra is not underlain by permafrost, so photosynthesis and most other biological activities continue (albeit slowly) throughout the year. A variety of plant growth forms are present in tropical alpine tundra, including low-growing shrubs, perennials, and grasses.

Many tundra plants have hairy leaves that trap heat. The flowers of some species move over the course of the day, tracking the sun's warmth. Most animals are either summer

BOREAL and TEMPERATE EVERGREEN FOREST

Bull moose (*Alces alces*) in boreal forest, Alberta, Canada

Southern beech (*Nothofagus*) in the temperate evergreen forest of Fiordland National Park, New Zealand

Community composition

Dominant plants

Trees, shrubs, and perennial herbs

Species richness

Plants: Low in trees, higher in understory
Animals: Low, but with summer peaks in migratory birds

Soil biota

Very rich in deep litter layer

The boreal owl (*Aegolius funereus*) feeds on insects and small birds and mammals of the coniferous evergreen forests of Europe and North America. The owl lives in the forests year-round, dispersing occasionally when food becomes extremely scarce.

migrants or are dormant for much of the year. Resident birds and mammals, such as the willow ptarmigan (*Lagopus lagopus*) and Arctic fox (*Vulpes lagopus*), have thick fur or feathers that may change color with the seasons, from brown in summer to white in winter.

Evergreen trees dominate boreal and temperate evergreen forests

The boreal forest biome (also known as taiga) occurs at latitudes below Arctic tundra and at elevations below alpine tundra on temperate-zone mountains. Winters in the boreal forest are long

and very cold; summers are short, although often relatively warm. The boreal forests of the Northern Hemisphere are dominated by coniferous gymnosperm species such as spruces and firs. The evergreen leaves of conifers are needlelike rather than flat; their reduced surface area cuts down on evaporative water loss. The short summers favor evergreen leaves, which are ready to photosynthesize as soon as temperatures warm. In winter, downward-drooping limbs allow the trees to shed snow easily.

The dominant mammals of the boreal forest, such as moose and hares, eat leaves, but the seeds in conifer cones support a variety of rodents, birds, and insects. Many small mammals

TEMPERATE DECIDUOUS FOREST

Fallen oak leaves on the winter forest floor, New York State

Black bears (*Ursus americanus*) are common in North American deciduous forests.Mourning cloak butterflies (*Nymphalis antiopa*) overwinter as adults, settled in crevices and under tree bark in the deciduous forests of eastern North America. Their early appearance is a harbinger of spring.**Community composition****Dominant plants**

Trees and shrubs

Species richness**Plants:** Many tree species in southeastern U.S. and eastern Asia, rich shrub layer**Animals:** Rich; many migrant birds, richest amphibian communities on Earth, rich summer insect fauna**Soil biota**

Rich

hibernate in winter, but voles, lemmings, and mice remain active under the snowpack, serving as food for predators such as foxes and owls.

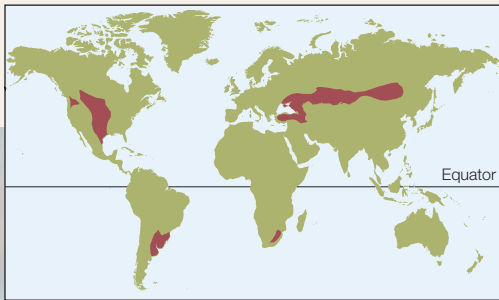

Temperate evergreen forests grow along the coasts of continents in both hemispheres at middle to high latitudes, where winters are mild and wet and summers are cool and dry. In the Northern Hemisphere, the dominant trees in temperate evergreen forests are conifers, some of which are the world's most massive tree species (including the giant sequoia and coast redwood). In the Southern Hemisphere, the dominant trees are southern beeches (*Nothofagus*), some of which are evergreen.

Temperate deciduous forests change with the seasons

The temperate deciduous forest biome is found in eastern North America, eastern Asia, and Europe. Temperatures in these regions fluctuate dramatically between summer and winter, although precipitation is fairly evenly distributed throughout the year. Deciduous trees, which dominate these forests, lose their leaves during the cold winters and produce new leaves that photosynthesize rapidly during the warm, moist summers.

Many more tree species live here than in boreal forests. The temperate forests richest in species are those of the southern

TEMPERATE GRASSLANDS

American bison herd grazing shortgrass prairie, North Dakota

Community composition

Dominant plants

Perennial grasses and forbs

Species richness

Plants: Fairly high

Animals: Relatively few birds because of simple structure; mammals fairly rich

Soil biota

Rich

The flightless Darwin's rhea (*Rhea pennata*) grazes the grasslands of Patagonia.

Przewalski's horse in Khustain Nuruu National Park, Mongolia

Appalachian Mountains of the United States and those found in eastern China and Japan—areas that were not covered by glaciers during the Pleistocene. Many plant genera are shared among the three geographically separate regions where this biome is found.

Although many animals are permanent residents of deciduous forests, some (including many birds) migrate to escape the winter cold. Others that remain through the winter acquire massive fat stores in fall and hibernate (see Section 40.5), often in underground burrows. Many insects pass the winter in a state of diapause (suspended development), the onset of which is triggered by the decreasing hours of daylight—a reliable predictor of winter.

Temperate grasslands are widespread

Temperate grasslands are found in many parts of the world, all of which are relatively dry for much of the year. Most grasslands, such as the pampas of Argentina, the veldt of South Africa, and the Great Plains of North America, have hot summers and relatively cold winters. In some grasslands, most of the precipitation falls in winter (as in California grasslands); in others, the majority falls in summer (as in the Great Plains and the Russian steppe).

Grassland vegetation is structurally simple but rich in species of perennial grasses and forbs (herbaceous plants other than grasses). This abundant plant biomass supports herds

HOT DESERT

Gemsbok (*Oryx gazella*) on the dunes, Namib-Naukluft National Park, Namibia

Community composition

Dominant plants

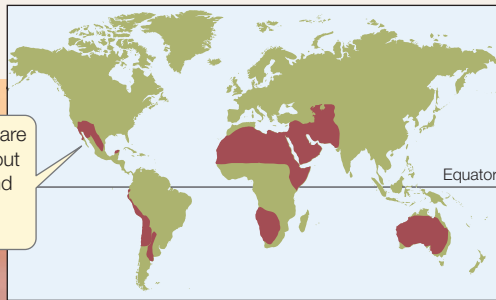

Many different growth forms (but few or no trees)

Species richness

Plants: Moderately rich; many annuals
Animals: Very rich in rodents; richest bee communities on Earth; very rich in reptiles and butterflies

Soil biota

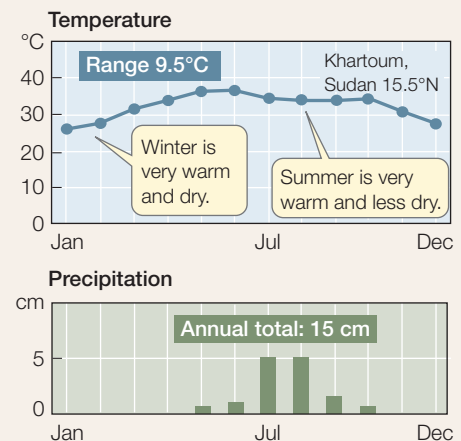

Few species

Succulents such as agave, candelabra, and cardon characterize the deserts of the North American Southwest.

The fog-basking beetle (*Onymacris unguicularis*) retrieves the water it needs to survive from the morning fogs of Africa's Namib Desert.

of large grazing mammals. Grassland plants are adapted to grazing and to fire. They store much of their energy underground and resprout quickly after being burned or grazed. There are comparatively few trees in temperate grasslands because trees cannot survive the periodic fires. If grasslands do not burn periodically, many of the species that typify this biome will be replaced by fire-intolerant species that are superior competitors.

The topsoil of grasslands is usually rich and deep, and thus exceptionally well suited to growing crops such as corn and wheat. As a consequence, most of the world's temperate

grasslands have been turned over to agriculture and no longer exist in their natural state.

Hot deserts form around 30° latitude

The hot desert biome is concentrated in two belts, centered around 30°N and 30°S latitude (where warm, dry air descends and picks up moisture; see Figure 54.3). The driest of these regions, where rains rarely penetrate, are far from the oceans, as in the center of Australia and the middle of the Sahara in Africa.

Desert plants have several structural and physiological adaptations that help them conserve water, as described in

COLD DESERT

Vicuña (*Vicugna vicugna*) family herd in Andean desert, Lauca National Park, Chile

A cold desert in northern New Mexico, at about 2,000 meters in elevation, is dominated by juniper shrubs (*Juniperus* sp.).

Community composition

Dominant plants

Low-growing shrubs and herbaceous plants

Species richness

Plants: Few species

Animals: Rich in seed-eating birds, ants, and rodents; low in all other taxa

Soil biota

Poor in species

Living in a cold desert presents special challenges to a poikilotherm. This collared lizard (*Crotaphytus* sp.) in Bluff, Utah, is warming itself by basking on a rock.

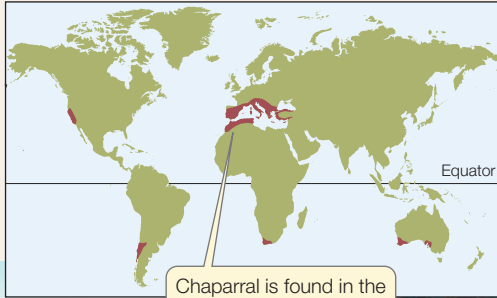

Section 39.3. Many desert plants are xerophytes: species with adaptations for reducing water loss or storing water. The aboveground parts of many desert plants are covered with a waxy cuticle to prevent water loss; leaves may be reduced to spines to minimize surface area, as in the Cactaceae of the Western Hemisphere and the Euphorbiaceae in much of the rest of the world. Other desert plants are succulents that store water in fleshy leaves or stems. Most perennial plants go dormant during dry seasons, and then grow rapidly as soon as rains return. Their seeds tend to be heat- and drought-resistant and accumulate in a dormant state in the soil.

Small desert animals are inactive during the hottest part of the day, remaining in underground burrows. Desert mammals have physiological adaptations for conserving water, including a reduced number of sweat glands and kidneys that produce highly concentrated urine. Many desert animals require no water beyond what they can extract from the carbohydrates in their food.

Cold deserts are high and dry

The cold desert biome is found in dry regions at mid- to high latitudes, especially in the interiors of continents where mountain ranges block moisture-rich air (see Figure 54.8). Blocked by

CHAPARRAL

Chaparral is found in the Mediterranean region and on the western coasts of continents.

A Spanish ibex (*Capra pyrenaica*) among maquis, a chaparral vegetation found in Spain and Corsica.

Maritime chaparral on Montara Mountain in California's San Mateo County. The light green shrubs in the foreground are *Arctostaphylos montaraensis*, a species that is endemic to this mountain.

Community composition

Dominant plants

Low-growing shrubs and herbaceous plants

Species richness

Plants: Extremely high in South Africa and Australia

Animals: Rich in rodents and reptiles; very rich in insects, especially bees

Soil biota

Moderately rich

Two fynbos species, the Cape sugarbird (*Promerops cafer*) and its nectar source, the pincushion protea (*Leucospermum cordifolium*) in Helderberg Nature Reserve, South Africa.

two mountain ranges (the Andes and the Chilean Coast range), the Atacama Desert is the driest place on Earth; average yearly rainfall is less than 1 millimeter.

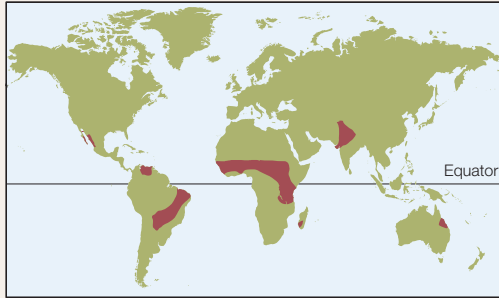

Cold deserts are dominated by a few species of low-growing shrubs. The surface layers of the soil are recharged with moisture in winter, and plant growth is concentrated in spring. Cold deserts are relatively species-poor, but the plants that do grow there tend to produce large numbers of seeds, supporting many species of seed-eating birds, ants, and rodents. Burrowing behavior is widespread among cold desert dwellers but—in contrast to hot desert animals—they burrow to escape cold temperatures, not excessive heat.

Chaparral has hot, dry summers and wet, cool winters

The chaparral biome is found on the western coasts of continents at mid-latitudes (around 40°). Winters in this biome are cool and wet; summers are warm and dry. Such climates are found in the Mediterranean region of Europe (for which the Mediterranean climate is named), coastal California, central Chile, extreme southern Africa, and southwestern Australia. The fynbos of the Cape region of South Africa, described at the opening of this chapter, is part of the chaparral biome.

The dominant plants of chaparral vegetation are low-growing shrubs and trees with tough evergreen leaves that conserve water.

THORN FOREST and TROPICAL SAVANNA

Family groups of African elephants (*Loxodonta africana*) in Kenya's Ol Malo Wildlife Sanctuary converge into a large herd for migration.

Madagascar ocotillo (*Alluadia procera*) dominate this thorn forest.

Community composition

Dominant plants

Shrubs and small trees; grasses

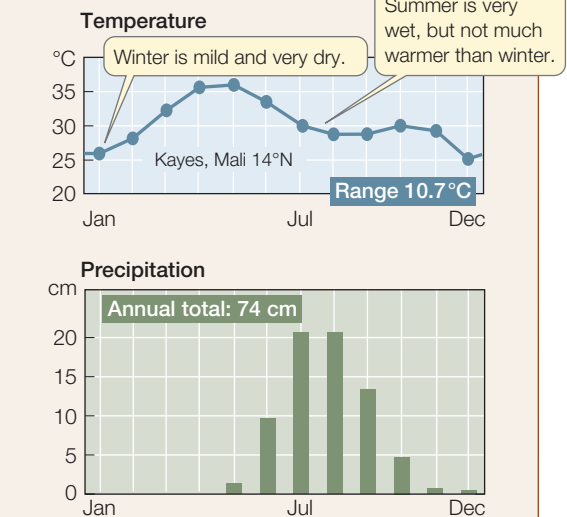

Species richness

Plants: Moderate in thorn forest; low in savanna

Animals: Rich mammal faunas; moderately rich in birds, reptiles, and insects

Soil biota

Rich

Termite colonies build huge mounds on the African savanna, providing a food source for mammals such as this baboon (*Papio* sp.).

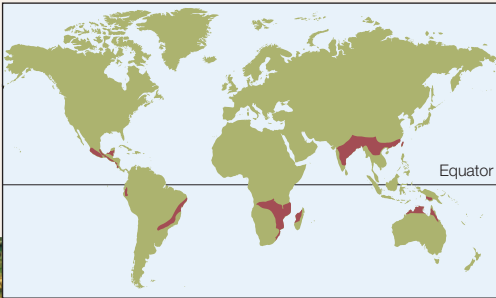

The shrubs carry out most of their growth and photosynthesis in early spring, when insects are active and birds breed. Many chaparral species produce strong-smelling defensive chemicals to reduce losses of their hard-to-replace foliage to herbivores. Annual plants are abundant and produce large quantities of seeds that fall onto the soil, supporting many small rodents, most of which store seeds in underground burrows. Burrowing to avoid midday heat and nocturnal foraging are strategies used by many chaparral animals. Chaparral vegetation is adapted to periodic fires; the seeds of some species do not germinate until after they have survived a fire. Many shrubs of Northern Hemisphere chaparral produce bird-dispersed fruits that ripen in late fall,

when large numbers of migrant birds arrive from the north. In the fynbos of South Africa, seeds equipped with elaiosomes are transported by ants, which bury them deep enough to survive the periodic fires.

Thorn forests and tropical savannas have similar climates

The thorn forest and tropical savanna biomes are found primarily at latitudes below the hot deserts of Africa, South America, and Australia. Little or no rain falls in these biomes in winter, but rainfall may be heavy during summer. Thorn forests contain many plants similar to those found in hot deserts,

TROPICAL DECIDUOUS FOREST

A forest canopy of pijo trees (*Cavanillesia platanifolia*) during the dry season in Cerro Blanco on the Ecuadorian coast

Bengal tiger (*Panthera tigris tigris*) in the forests of Bandhavgarh, India.

Community composition

Dominant plants

Deciduous trees

Species richness

Plants: Moderately rich in tree species

Animals: Rich mammal, bird, reptile, and amphibian communities; rich in insects

Soil biota

Rich, but poorly known

Hummingbirds such as *Amazilia tzacatl* are major pollinators in this biome.

including succulents. The dominant plants are spiny shrubs and small trees, many of which drop their leaves during the long, dry winter. Trees of the genus *Acacia* are common in thorn forests and savannas worldwide. In Africa, *Andansonia* (baobab) trees are also a hallmark of these biomes.

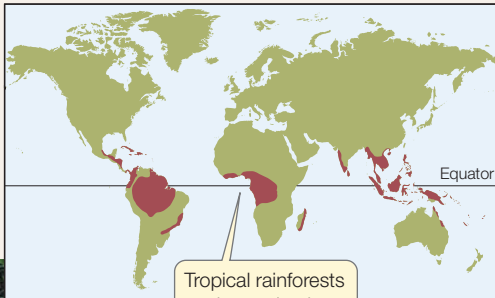

Savanna is characterized by expanses of grasses and grass-like plants surrounding scattered individual trees. The largest tropical savannas are found in central and eastern Africa, where they are populated by herds of grazing and browsing mammals and the large carnivores that prey on them. The migration of vast herds of herbivores in search of “greener

pastures” during the dry season is another characteristic of this impressive region. Grazers and browsers maintain the savannas by disproportionately damaging shrubs and trees, which cannot withstand as much tissue loss as can the grasses. If savanna vegetation is not grazed, browsed, or burned, it typically reverts to dense thorn forest.

Tropical deciduous forests occur in hot lowlands

As the temperature and the length of the rainy season increase toward the equator, the tropical deciduous forest biome replaces thorn forest. Tropical deciduous forests have taller trees

TROPICAL RAINFOREST

Tropical rainforests are located at low latitudes.

The canopy of an Ecuadoran tropical rainforest, seen from above

A golden lion tamarin (*Leontopithecus rosalia*) near Rio de Janeiro, Brazil

Community composition

Dominant plants

Trees and vines

Species richness

Plants: Extremely high

Animals: Extremely high in mammals, birds, amphibians, and arthropods

Soil biota

Very rich but poorly known

The three-toed sloth (*Bradypus variegatus*) is almost totally arboreal, spending its life in the rainforest canopies of Central and South America.

and fewer succulent plants than thorn forests or savannas, and they support a much greater number of plant and animal species. Most of the trees, except for those growing along rivers, lose their leaves during the long, hot dry season. Growth increases in the rainy season; many plants flower while they are still leafless.

Most plant species in this biome are pollinated by animals. In the Sierra Madre Occidental, a mountain range in the extreme southwestern United States extending into western Mexico, tropical deciduous forests are part of a “nectar corridor,” a series of patches of flowering plants that are used

as refueling stops by long-distance migrants traveling north from overwintering sites to their breeding sites in the Rocky Mountains.

The soils of this biome are among the best in the tropics for agriculture because they contain more nutrients than the soils of wetter areas. As a result, most tropical deciduous forests worldwide have been cleared for agriculture and grazing.

Tropical rainforests are rich in species

The tropical rainforest biome, or simply the rainforest, is found in equatorial regions where total rainfall exceeds 250 centimeters

Walter Climate Diagrams

Original Source

Devised by the German biogeographer Heinrich Walter in 1979, this graphic technique plots temperature and precipitation data in a simple way that visualizes a “growing season”—those months when average temperatures are above 0°C and the average precipitation trace falls above the temperature trace.

Analyze the Data

Walter climate diagrams are predicated on the “rule of thumb” that plant growth requires temperatures above 0°C and at least 20 mm of precipitation for each 10°C above 0°. They have two y-axis scales, one for temperature and one for precipitation; these axes align 0 mm of precipitation with a temperature of 0°C. The x axis shows the 12 months, with the summer solstice placed in the center of the x axis.

The Walter diagram shown at the right is for London, England. Average yearly temperature and precipitation data for three other cities are given in the table. Using these data, create Walter diagrams for each city. Use your diagrams along with the information in the preceding sections of this chapter to answer the questions.

QUESTION 1

Based solely on your diagrams, which biome do you think is represented by each location? What physical attribute other than temperature and precipitation might significantly affect the biomes of these locations?

QUESTION 2

How do you explain the temperature disparity between London and Moscow, both of which lie in a similar latitude of Europe?

QUESTION 3

Perth lies on the western coast of Australia, in the Southern Hemisphere. How does this affect the configuration of your Walter diagram? (Hint: Where did you place the summer solstice?) Without considering this climate data, what biome would you expect to find based solely on Perth’s latitude and coastal location?

Go to **BioPortal** for all **WORKING WITH DATA** exercises

annually and the dry season lasts no longer than 2 or 3 months. With no seasons unsuitable for growth, it is the most species-rich of all biomes, with up to 500 species of trees per square kilometer. Although these forests cover less than 2 percent of Earth’s surface, they are home to more than half of all known species.

Along with the immense number of species they support, rainforests have the highest overall productivity of all terrestrial ecological communities. However, most mineral nutrients are tied up in the vegetation. The soils usually cannot support agriculture without massive applications of fertilizers. These forests are home to many epiphytes—plants that grow on other plants, deriving their nutrients and moisture from air and water rather than soil.

The rainforests provide humans with a dazzling range of products, including fruits, nuts, medicines, fuel, pulp, and furniture wood. Many more useful species undoubtedly await discovery, as only a small proportion of this biome’s species have been inventoried. The rainforests, however, are currently

being cut down or converted to agriculture at a rate of almost 20 million hectares per year.

RECAP 54.3

Ecologists recognize several terrestrial environment types called biomes. The geographic distribution of biomes is determined primarily by temperature and precipitation, but is also influenced by soil characteristics and fire.

- How do temperate grasslands differ from tropical savannas? In what ways are they similar? [See pp. 1131 and 1135](#)
- What primary factor distinguishes a tropical biome? [See pp. 1135–1137](#)

About 70 percent of Earth’s surface is covered by saltwater oceans and seas that support abundant life. The small percentage of the aquatic world that consists of fresh water also hosts a significant proportion of Earth’s aquatic organisms.

54.4 How Is Life Distributed in Aquatic Environments?

Aquatic biomes do not depend on plants for their structure in the way that terrestrial biomes do. Salinity is the primary factor that distinguishes the aquatic biomes. The marine biome is characterized by salt water, freshwater biomes by low salinity, and estuaries by the mixing of fresh water and salt water.

The marine biome can be divided into several life zones

Earth's oceans form one large, interconnected water mass on which the atmospheric factors that distinguish terrestrial biomes have little influence. However, light penetration, water temperature, water pressure, water movement (i.e., waves and tides), and salinity all vary spatially, so most marine organisms have restricted ranges and display adaptations to particular physical conditions.

The physical and biological discontinuities within the marine biome divide it into several distinct **life zones** (Figure 54.9). These zones are identified principally by their distance from shore and from the water's surface. The depth of an ocean basin varies from the shoreline to the relatively shallow continental shelf and to the deepest part of the ocean, sometimes known as the abyssal plain.

Water depth affects how much light is available to sustain the photosynthetic organisms that form the base of the marine food chain. In both marine and freshwater environments, the

layer of water reached by enough sunlight to support photosynthesis is called the **photic zone**. Approximately 90 percent of all aquatic life is found in the photic zone.

The **coastal zone** extends from the shoreline to the edge of the continental shelf; it is characterized by relatively shallow, well-oxygenated water and relatively stable temperatures and salinities. These conditions support high densities of phytoplankton (photosynthetic floating protists), which in turn support some of the world's most important fisheries. Structure in coastal-zone communities may be provided by a variety of organisms. In warm coastal waters, corals generate complex reef structures that support ecosystems rivaling the rainforest in diversity. "Forests" of multicellular algal species (seaweeds and giant kelps) grow along many coasts at higher latitudes.

The area of the coastal zone that is affected by wave action is called the **littoral zone**. The principal autotrophs in this zone—sea grasses and algae—are consumed by a variety of invertebrates as well as small fishes. The portion of the coastal zone lying between the high and low tide levels is the **intertidal zone**, where tidal movements create conditions of highly variable temperature and salinity. Intertidal organisms, including clams, barnacles, copepods, and burrowing worms, are alternately exposed to air and submerged under water.

Throughout most of the oceans, the dominant autotrophs are phytoplankton. In the open ocean, or **pelagic zone**, the principal consumers of phytoplankton are zooplankton—mainly small crustaceans and larval stages of marine animals—which

54.9 Life Zones of the Marine Biome The ocean's life zones are primarily determined by light penetration. More than 90 percent of ocean-dwelling species live in the sunlit photic zone, which comprises less than 2 percent of the volume of open water. Wave action and exposure to air affect those life zones where the ocean meets the shore.

Forests of giant kelp (*Macrocystis* sp.) dominate many coastal communities.

A large sailfin (*Istiophorus albicans*) feeds on sardines (*Sardinella aurita*) in pelagic waters of the Gulf of Mexico.

Heat and minerals from hydrothermal vents nourish unique deep-ocean communities.

54.10 Life Zones in a Freshwater Lake Like oceans, standing bodies of fresh water can be divided into life zones based on water depth and distance from shore.

A school of bleak (*Alburnus scoranza*) among giant reeds along a lakeshore in Macedonia.

An osprey (*Pandion haliaetus*) snatches a large fish from the open waters of a Canadian lake.

in turn support many larger free-swimming vertebrate and invertebrate species.

The ocean bottom—the sediment surface—is referred to as the **benthic zone**. Many benthic organisms are adapted to life on the seafloor substrate. They include sessile animals such as sponges, bryozoans, ribbon worms, and brachiopods as well as motile bottom feeders such as crabs and sea slugs.

Where the water is too deep for light to penetrate, little photosynthesis can take place, and both plant and animal diversity are low. Depths reached by less than 1 percent of incoming sunlight constitute the **aphotic zone**. Many of the organisms inhabiting these regions subsist on decaying organic matter that sinks down from the photic zone. Some produce their own light by means of bioluminescent organs (see Figure 33.14D). Even deep-ocean trenches and rift valleys support hydrothermal vent ecosystems sustained by chemoautotrophic prokaryotes that can metabolize the nutrients in seawater without the aid of sunlight (see Section 26.3).

Freshwater biomes may be rich in species

In contrast to the vast oceans, bodies of fresh water cover less than 3 percent of Earth's surface, but they are home to about 10 percent of all aquatic species. Freshwater biomes, as the name implies, are characterized by low levels of salinity—generally below 1 percent.

Freshwater biomes are distinguished by the degree and direction of water movement. The water in streams and rivers flows (generally) in one direction, from the source to the mouth. Lakes and ponds are bodies of standing water. Wetlands constitute an intermediate biome, with water levels that fluctuate.

Lakes and ponds are found on every continent. They vary in size and persistence: some small ponds may exist for only a single season, whereas lakes thousands of square kilometers in size can persist for centuries or longer. Like the oceans, bodies of standing water can be divided into life zones based on depth and distance from shore (Figure 54.10). The zone along the shoreline is characterized by warm temperatures and high

species diversity. The photic upper layers of the open-water zone of open water teem with phytoplankton and the fish that feed on them; below that lies an aphotic zone where little light penetrates, oxygen levels are low, and there is little biotic diversity. As in the marine biome, the benthic zone comprises the sediments and other substrates at the lake bottom.

The physical features of a stream or river change along its length as water flows from the point of origin (the source) to its mouth, where it empties into a lake or an ocean. The source of a stream or river may be snowmelt, a spring, or a lake. The headwaters (those close to the source) tend to be cool, fast-flowing, and well oxygenated. As a river flows downstream, it widens, its rate of flow slows, and it supports a higher diversity of plant and animal life. At the mouth, sediment can accumulate, reducing light penetration and oxygen levels. The animal inhabitants of streams and rivers vary along their length as well. For example, rainbow trout (*Oncorhynchus mykiss*), which lay their eggs in gravel beds and use visual cues to find their prey, thrive in the clear, unsedimented headwaters. Certain catfish, by contrast, tolerate the oxygen-depleted, murky shallow waters near the mouths of rivers by exchanging gases through their skin and locating prey by chemical rather than visual cues.

The freshwater wetland biome is highly variable in terms of size and persistence. Swamps, marshes, and bogs are all forms of freshwater wetlands. The unifying characteristic of freshwater wetlands is intermittent flooding. The fluctuations in water level are due to inputs in the form of groundwater, surface water, and rainwater and outputs in the form of evapotranspiration, water flow below the surface, and surface runoff. Plants found in freshwater wetlands include duckweed and other floating water plants with tiny roots, emergent water plants with roots that are completely submerged, such as cattails, and trees and shrubs that grow on the margins. Although many kinds of animals are found in wetlands, frogs and other amphibians, which have a life cycle with both aquatic and terrestrial phases, fare especially well in these water-saturated terrestrial environments.

Estuaries have characteristics of both freshwater and marine environments

Estuaries form where rivers meet the ocean and salt water mixes with fresh water. Depending on local conditions, estuarine environments vary in size and species composition. In the upper part of the intertidal zone, estuaries can support salt marshes, with salt-tolerant rushes, grasses, and low-growing shrubs. Mangrove forests can be found along shorelines and in river deltas in tropical and subtropical latitudes. Dominating these forests are mangroves (*Rhizophora*). These trees display many remarkable adaptations—including aerial roots that are impervious to salt—that make them highly tolerant of high salinity, periodic anoxia, and occasional inundation. Sea grass beds can form in the subtidal zone, dominated by flowering plants such as eelgrass (*Zostera*) that can survive entirely underwater.

Diversity in estuaries tends to be very high. Having characteristics of both freshwater and marine systems, estuaries are home to many unique species and play an important role for other species as a conduit between marine and freshwater environments. Some salmon species that hatch in rivers, for example, spend many months in estuaries adjusting to higher salinities before swimming out to sea to grow into adults. The importance of estuaries as nurseries of marine life cannot be overstated.

Estuarine environments have long been a source of benefits for humans, not the least of which is their role in purifying terrestrial runoff and groundwater. In many places around the world, however, overfishing, habitat destruction, and pollution threaten the viability of estuarine ecosystems.

RECAP 54.4

The marine biome can be divided into several life zones determined by distance from the surface, which influences how much light is available to sustain photosynthesis, and distance from shore. Lakes and ponds, which are freshwater biomes, are also divided into life zones according to water depth and light penetration. Salt and fresh water mix in bodies of water known as estuaries.

- How does light penetration affect diversity in different life zones of the oceans? [See p. 1139 and Figure 54.9](#)
- How do estuaries link freshwater and marine systems, and why is this biome so important? [See p. 1141](#)

Biomes and life zones have similar physical characteristics in different parts of the world, and biome-adapted organisms share similar characteristics in widely separated regions. Yet biomes in different regions rarely have particular species in common, so climate alone cannot explain why species live where they do.

54.5

What Factors Determine the Boundaries of Biogeographic Regions?

Climate interacts with local abiotic features to influence where and how organisms live, but these are not the only factors that determine where organisms can be found. Evolutionary history—where and when groups of organisms originated and

diverged—is key to determining the distributions of organisms. Evolutionary history, in turn, is greatly influenced by geological history, which has had a profound influence on the dispersal of species.

Geological history influences the distribution of organisms

Until European naturalists traveled the globe in the nineteenth century, they had no way of knowing how organisms were distributed in other parts of the world. Alfred Russel Wallace, who along with Charles Darwin advanced the idea that natural selection could account for the evolution of life on Earth (see Section 21.1), was one of those global travelers. Wallace spent seven years in the Malay Archipelago, where he noticed some remarkable patterns in the distributions of organisms. For example, he described the dramatically different birds that inhabited the adjacent islands Bali and Lombok:

In Bali we have barbets, fruit-thrushes and woodpeckers; on passing over to Lombok these are seen no more, but we have an abundance of cockatoos, honeysuckers, and brush-turkeys, which are equally unknown in Bali, or any island further west. The strait here is fifteen miles wide, so that we may pass in two hours from one great division of the earth to another, differing as essentially in their animal life as Europe does from America.

Wallace pointed out that these differences could not be explained by climate or by soil characteristics, because in those respects Bali and Lombok are essentially identical.

Wallace saw that, based on the distributions of plant and animal species, he could draw a line that divided the Malay Archipelago into two distinct halves (**Figure 54.11**). He correctly deduced that the dramatic differences in flora and fauna were related to the depth of the channel separating Bali and Lombok. This channel is so deep that it would have remained full of water, and thus would have been a barrier to the movement of terrestrial animals, even during the glaciations of the Pleistocene epoch, when sea level dropped more than 100 meters and Bali and the islands to the west were connected to the Asian mainland.

With these insights, Wallace established the conceptual foundations of **biogeography**, the scientific study of the patterns of distribution of populations, species, and ecological communities across Earth. In *The Geographical Distribution of Animals*, published in 1876, he detailed the factors known at the time that influence the distributions of animals, including past glaciation, land bridges, deep ocean channels, and mountain ranges. He earned some measure of scientific immortality in that the Malay discontinuity that first piqued his curiosity is known to this day as “Wallace’s line.”

The biotas of different parts of the world differ enough to allow us to divide Earth into several continental-scale areas called **biogeographic regions** (**Figure 54.12**), each containing characteristic assemblages of species occupying many different biomes. The boundaries of these biogeographic regions are drawn where assemblages of species change dramatically, often over short distances. The biotas of biogeographic regions

54.11 Wallace's Line Wallace's line corresponds to a deep-water channel between the islands of Bali and Lombok. This channel would have blocked the movement of terrestrial organisms even during the Pleistocene glaciations, when sea level was 100 meters lower than it is today.

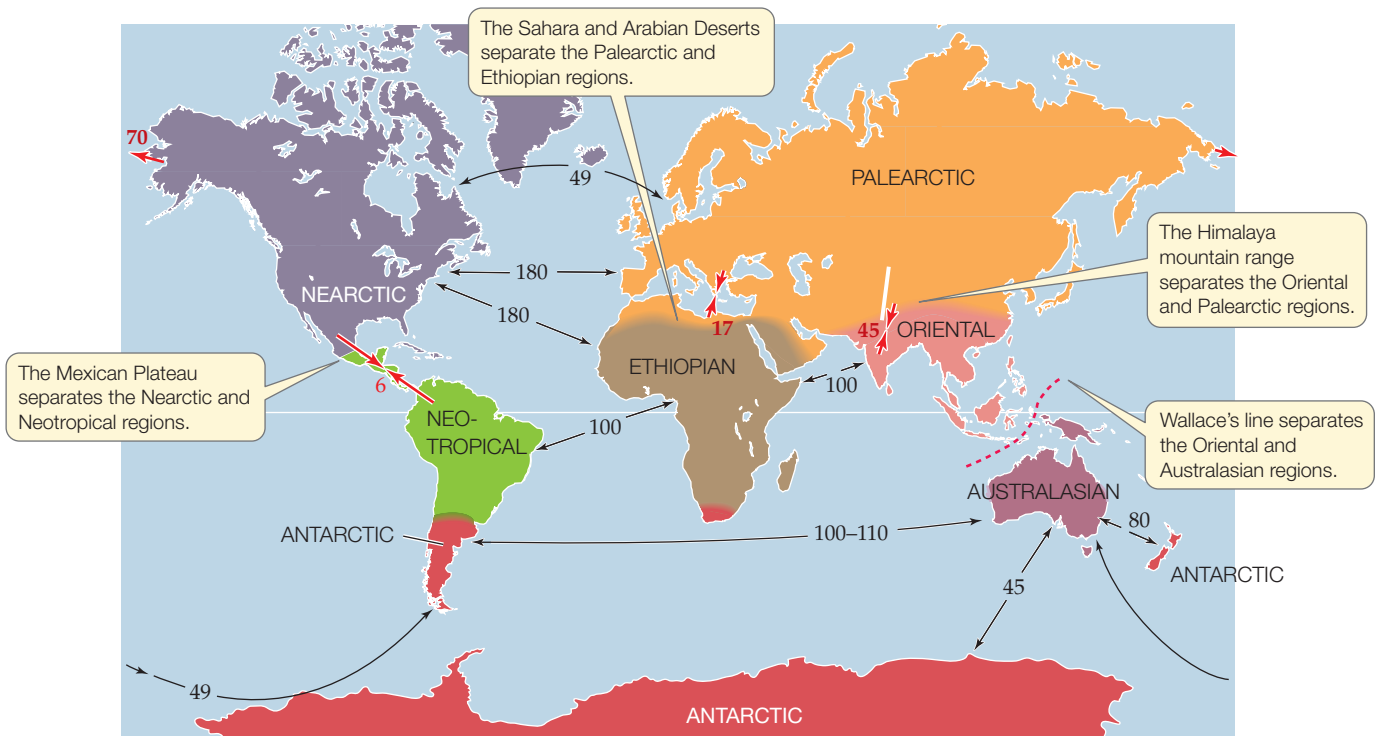

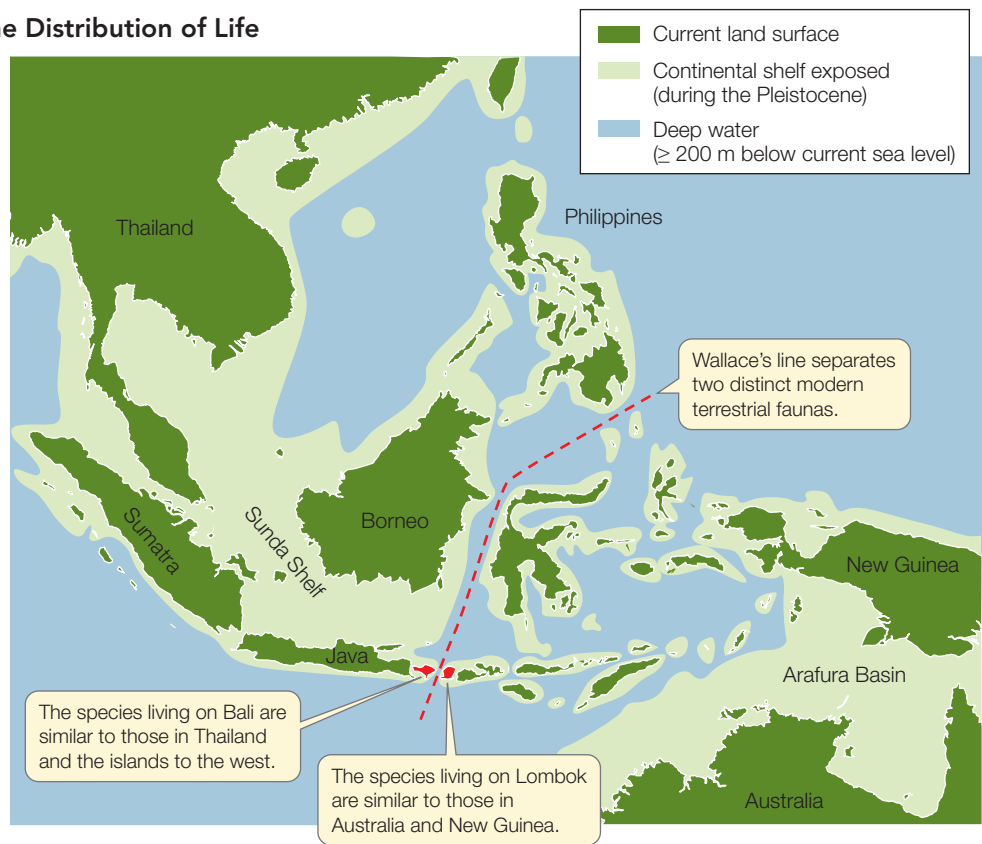

differ because oceans, mountains, deserts, and other barriers restrict the dispersal of organisms from one region to another. Although organisms do disperse between adjacent biogeographic regions, such interchanges have not been frequent or massive enough to eliminate the striking differences between them.

Go to Activity 54.1
Major Biogeographic Regions
Life10e.com/ac54.1

Two scientific advances changed the field of biogeography

For many decades after observing that the biotas of the major biogeographic regions are strikingly different, biogeographers speculated about the causes of these differences. The field remained primarily descriptive, however, until the second half of the twentieth century when two

scientific advances transformed biogeography into a dynamic, multidisciplinary field. These advances were (1) the acceptance of the theory of continental drift and (2) the development of phylogenetic taxonomy.

54.12 Earth's Biogeographic Regions The major biogeographic regions are separated by climatic, topographic, and/or aquatic barriers to dispersal that cause their biotas to differ strikingly from one

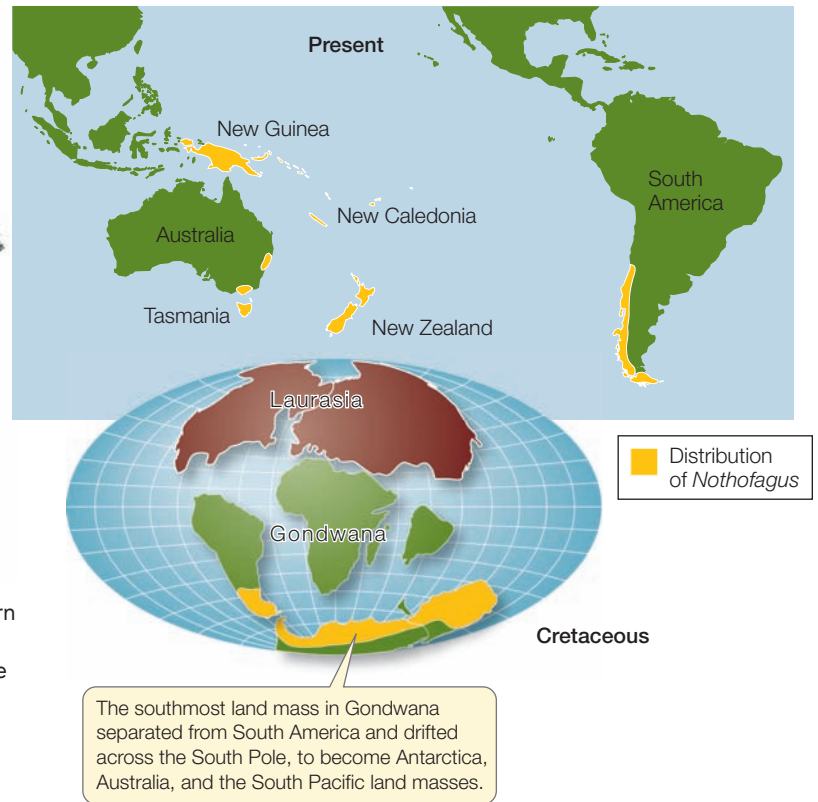

another. The red arrows on the map show the time (in millions of years) since land masses came together. Black arrows show the time since land masses separated.

(A)

54.13 Nothofagus Has a Gondwanan Distribution The modern range of southern beeches (A) is best explained by their origin in Gondwana during the Cretaceous. (B) When Gondwana broke apart, *Nothofagus* remained in South America, Australia, New Zealand, and the islands of the South Pacific.

(B)

CONTINENTAL DRIFT By the 1960s scientists knew that continents can and do move (see Section 25.2). We now know that over the course of the Triassic and Jurassic periods, the supercontinent Pangaea divided into two great land masses, Laurasia and Gondwana (see Figure 25.12), which subsequently separated into the continents we know today. Those groups of organisms that are represented on two or more continents are believed to be ancient groups whose ancestors were widely distributed over these great land masses before they broke apart. After the breakup, however, their descendants evolved independently, so groups that did not originate until after the continents separated have more discrete distributions. Thus continental drift is at least partly responsible for the existence of the biogeographic regions shown in Figure 54.12.

Continental drift explains certain biogeographic distributions that would otherwise be difficult to understand. For example, the southern beeches—trees of the genus *Nothofagus*—are found in both the Neotropical and the Australasian biogeographic regions. Their distribution suggests that the genus originated in Gondwana during the Cretaceous period and was geographically separated by the breakup of that land mass (Figure 54.13).

What evidence do we have that *Nothofagus* did not simply leapfrog from one biogeographic region to another? Fossilized *Nothofagus* pollen from 55 to 34 million years ago has been found in Australia, New Zealand, western Antarctica, and South America, suggesting that *Nothofagus* was once continuously distributed across a single land mass (see Figure 54.13B). Moreover, the modern distribution of aphid genera that feed exclusively on *Nothofagus* parallels the distribution of the trees.

There are no air or water currents between Chile and New Zealand that would be likely to disperse insects, indicating that the aphids arose at a time when their host plants grew on a common land mass.

PHYLOGEOGRAPHY As we saw in Chapter 22, taxonomists have developed powerful methods of reconstructing the phylogenetic relationships among organisms. Biogeographers have adapted these methods to help them understand how organisms came to occupy their present-day distributions. Biogeographers can transform phylogenetic trees into **area phylogenies** by replacing the names of the taxa on a tree with the names of the places where those taxa now live or once lived.

Suppose, for example, we wonder why zebras, which are members of the horse family (Equidae), live in Africa when the fossil record indicates that the Equidae originated in North America. An area phylogeny of living equid species suggests that the ancestors of today's horses (represented by the oldest fossils) dispersed from North America to Asia, and then from Asia to Africa, and that the subsequent speciation of zebras took place entirely in Africa (Figure 54.14).

Go to Media Clip 54.1

Rafting to Madagascar

Life10e.com/mc54.1

Discontinuous distributions may result from vicariant or dispersal events

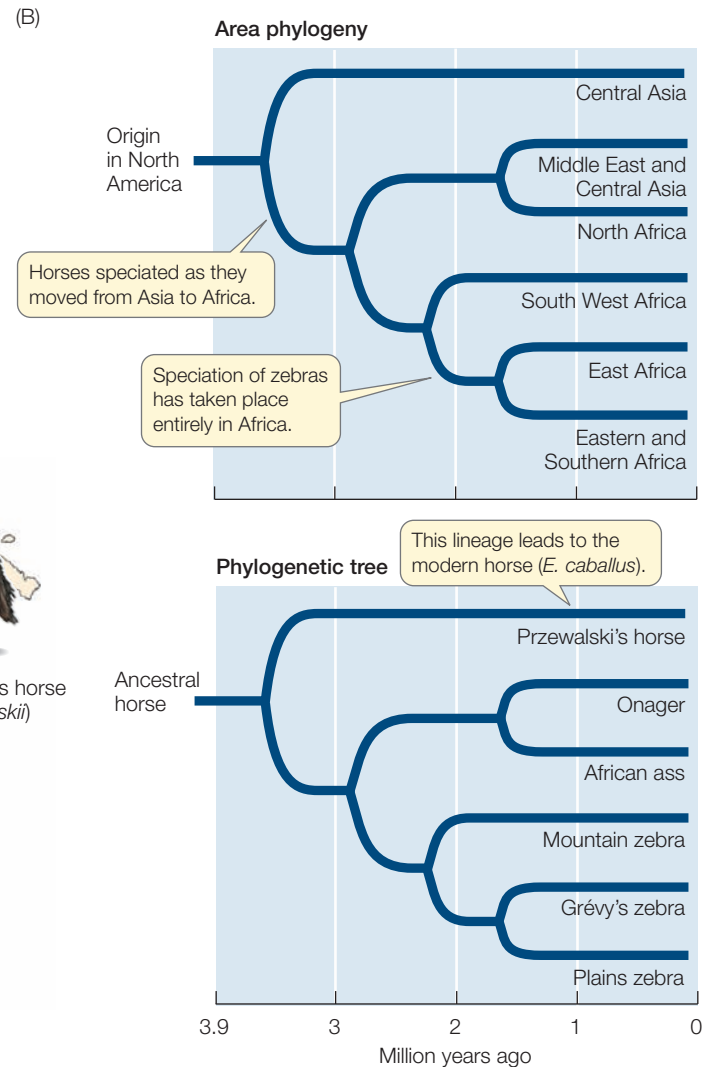

The appearance of a physical barrier to dispersal that splits the range of a species is called a **vicariant event**. A vicariant event

54.14 Phylogenetic Tree to Area Phylogeny The conversion of a phylogenetic tree into an area phylogeny helps biogeographers explain how the current distribution of a taxon came about. (A) The ancestor of all Asian and African equids (genus *Equus*; horses and

divides the species into two or more discontinuous populations, even though no individuals have dispersed to new areas. If, however, members of a species cross an existing barrier and establish a new population, the discontinuous range of the species is considered to be the result of dispersal.

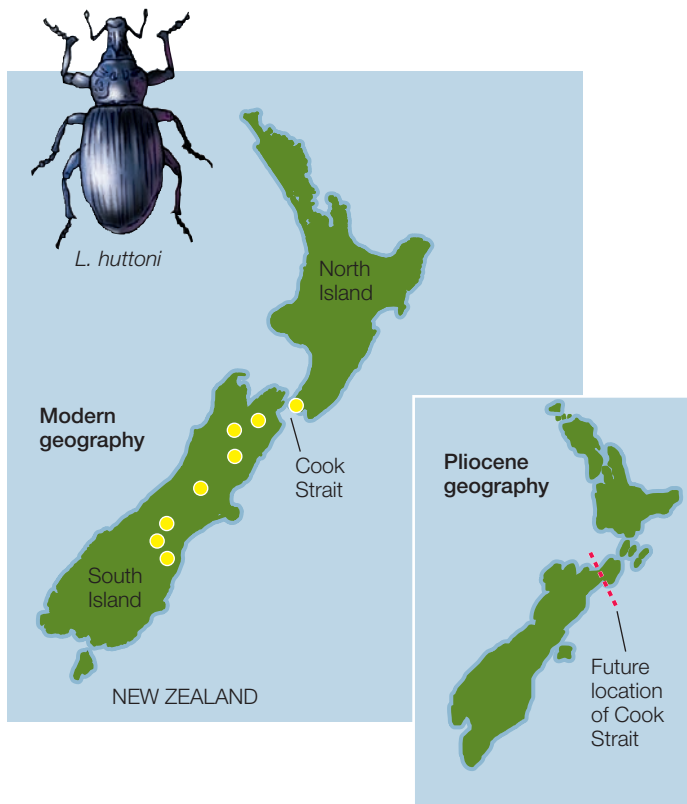

Given that the processes of vicariance and dispersal both influence distribution patterns, how can biogeographers determine the role of each process when reconstructing the evolutionary history of a particular species? By studying area phylogenies, a biogeographer may discover evidence suggesting that the distribution of an ancestral species was influenced by a vicariant event, such as continental drift or a change in sea level. If that inference is correct, then it is reasonable to assume

their relatives) migrated across the Bering Strait land bridge (light green) some 10 million years ago. (B) Organismal and area phylogenies explain the Asian and African distribution of the descendants of these ancestral horses.

that ancestral species in other lineages would have been affected by the same event and that similar distribution patterns should therefore be seen in other taxonomic groups. Differences in distribution patterns among taxonomic groups may indicate that they responded differently to the same vicariant events, that they diverged at different times, or that they had very different dispersal histories. By analyzing such similarities and differences, biogeographers seek to discover the relative roles of vicariant events and dispersal in determining today's distribution patterns.

The parsimony principle used in the reconstruction of phylogenies (see Section 22.2) can also be helpful in biogeographic studies. For example, the New Zealand flightless

54.15 A Vicariant Distribution Yellow circles indicate the current distribution of the flightless weevil *Lyperobius huttoni*. A comparison of New Zealand's present-day geography with its geography in the Pliocene, when the southern part of today's North Island was part of South Island, suggests that a vicariant event—a physical split separating populations—explains this distribution.

weevil *Lyperobius huttoni* is found in the mountains of South Island and on sea cliffs at the extreme southwestern corner of North Island (**Figure 54.15**). At first glance, its distribution might suggest that, even though this weevil cannot fly, some individuals in the distant past managed to cross Cook Strait, the 25-km wide body of water that separates the two islands. However, more than 60 other animal and plant species, including other flightless insects, are found on both sides of Cook Strait. Irrespective of their ability to fly, wade, or swim, it is unlikely that all 60 of these species made the same ocean crossing independently at different times over the course of their evolutionary history. In fact, geological evidence indicates that the present-day southwestern tip of North Island was once united with South Island. Thus a single vicariant event—the separation of the northern tip of South Island from the remainder of the island by the newly formed Cook Strait—could have produced the distribution pattern shared by all 60 species today.

In other cases, the evidence points to dispersal. There are, for example, more than 135 species of long-horned beetles endemic to the Hawaiian Islands. The islands have never been attached to any continent (they arose by volcanism from the

deep ocean floor), so no separation of continuous populations ever took place. Therefore this distribution must have been the result of long-distance dispersal. The beetles, which are most closely related to a genus found in North and Central America, probably colonized the islands and subsequently speciated as a consequence of specializing on different host plants on different islands (see Section 23.3).

Humans exert a powerful influence on biogeographic patterns

One more force capable of generating distribution patterns that span multiple biogeographic regions is human activity. Of the insects found both in Europe and in North America, it has been estimated that more than half have been transported between the continents by humans, either by accident or deliberately. Many of these transported species have unintended consequences for other species in their new regions. Where the fynbos has been invaded by the Argentine ant, for example, seedlings often fail to appear after fires. As we saw at the beginning of this chapter, the seeds of some fynbos plants survive fire only with the help of ants. The ants must be attracted to a seed, pick it up off the ground, nibble off the lipid-rich elaiosome, and then bury the seed deep enough in the soil to avoid injury by fire. Argentine ants, which humans accidentally transported to South Africa from South America, are attracted to the seeds and eat the elaiosomes, but these tiny ants are too small to carry off large seeds and they cannot bury seeds deep enough in the ground to survive fires. In places where Argentine ants have displaced native ant species, replacement of large-seeded plants by seedlings after fires can drop by tenfold compared with areas that have not been invaded. The effects of such accidental species introductions by humans will be discussed at length in Chapter 59.

RECAP 54.5

Earth can be divided into seven biogeographic regions, each with unique assemblages of species. Vicariant events generate distribution patterns by splitting the ranges of species; distribution patterns may also change when species disperse across barriers.

- What determines the boundaries of Earth's major biogeographic regions? How are these boundaries different from those of the biomes described in Section 54.3?
See p. 1126, p. 1141, and Figures 54.7 and 54.12
- Explain how the concepts of continental drift and phylogeography transformed the field of biogeography.
See pp. 1142–1143
- How do vicariance and dispersal interact to generate species distribution? **See pp. 1143–1145**

Earth's physical environment and geological history are major factors influencing the distribution of organisms. Next we will turn to the influence of organisms and populations of organisms on one another. Abiotic, intraspecific, and interspecific forces all interact in the complex processes of population dynamics.

What is it about the western edges of continents that promotes tough, shrubby plant communities such as fynbos?

ANSWER

The fynbos is an example of the chaparral biome found in the Mediterranean regions and on the western coasts of continents at mid-latitudes (around 40°). The Mediterranean climate promotes plant communities that are nurtured by cool, damp winters and can survive the dry summer conditions and periodic fire. Continental locations of this biome are related to the proximity of the cold ocean currents that flow toward the equator offshore (see Figure 54.5). The prevailing winds set up

rotating gyres of ocean water. Because of the direction of their rotation, warm water tends to move toward the poles along the east coasts of continents, whereas cool water moves toward the equator from higher latitudes along west coasts. These cool offshore currents bring cool, wet winters similar to those experienced by the Mediterranean region to large areas of continental western coastal regions.

CHAPTER SUMMARY 54

54.1 What Is Ecology?

- **Ecology** is the scientific investigation of interactions among organisms, between organisms and their physical environment, and the patterns of distribution and abundance resulting from these interactions.
- **Environmentalism** is the use of ecological knowledge to inform our decisions about the stewardship of natural resources.
- An organism's environment encompasses both **abiotic** (physical and chemical) components and **biotic** components (other living organisms).

54.2 Why Do Climates Vary Geographically?

- **Weather** refers to atmospheric conditions at a particular place and time. **Climate** is the average of atmospheric conditions, and the variation in those conditions, found in a particular place over an extended period of time.
- The solar energy that reaches a given unit of Earth's surface depends primarily on the angle of the sun's radiation, which in turn is a function of latitude. The tilt of Earth's axis results in seasonal variation in temperature and day length. **Review Figures 54.1, 54.2**
- Latitudinal variation in solar energy input drives atmospheric circulation patterns. **Review 54.3**
- Global surface wind patterns are driven by atmospheric circulation and Earth's rotation; these **prevailing winds** in turn drive ocean surface **currents**. **Review Figure 54.4, 54.5**
- Organisms respond to climatic challenges with physiological, morphological, and behavioral adaptations.

54.3 How Is Life Distributed in Terrestrial Environments?

- A **biome** is an environment that is shaped by its climatic and geographic attributes and characterized by ecologically similar organisms. **Review Figure 54.7**
- The distribution of terrestrial biomes is determined primarily by climate, but other factors, such as soil characteristics and fire, also influence vegetation.
- Biomes include Arctic and alpine tundra, boreal forest, temperate evergreen and temperate deciduous forests, temperate grasslands, hot and cold deserts, chaparral, thorn forest and savanna, tropical deciduous forest, and tropical rainforest.
See ANIMATED TUTORIAL 54.1, 54.2

54.4 How Is Life Distributed in Aquatic Environments?

- Aquatic biomes do not depend on plants for their structure in the way terrestrial biomes do. Salinity is the primary factor that distinguishes aquatic biomes.
- The marine biome is characterized by high salinity. Marine **life zones** are determined by distance from the surface, which influences how much light is available to sustain photosynthetic organisms, and by distance from the shore. **Review Figure 54.9**
- Freshwater biomes are distinguished by their water movement (standing versus flowing water). Standing water (lakes and ponds), like ocean basins, can be divided into life zones distinguished by depth and distance from shore. **Review Figure 54.10**
- The physical conditions in streams and rivers change along their length as water flows from the source to the mouth.
- In freshwater wetlands, water levels fluctuate because of variation in water input and output.
- **Estuaries** are bodies of water where salt and fresh water mix. This biome supports many unique species.

54.5 What Factors Determine the Boundaries of Biogeographic Regions?

- **Biogeography** is the scientific study of the patterns of distribution of populations, species, and ecological communities.
- The boundaries of the **biogeographic regions** are drawn where assemblages of species change dramatically over short distances. These boundaries are generally continental in scale and correspond to present or past barriers to dispersal. **Review Figures 54.11, 54.12, ACTIVITY 54.1**
- Continental drift explains some discontinuous distributions that include more than one biogeographic region. **Review Figure 54.13**
- Biogeographers can transform phylogenetic trees into **area phylogenies** to understand how organisms came to occupy their present-day distributions. **Review Figure 54.14**
- Both **vicariant events** and dispersal across barriers generate discontinuous species distributions. **Review Figure 54.15.**

CHAPTER REVIEW

REMEMBERING

- Ecology and environmentalism are
 - synonymous; the terms can be used interchangeably.
 - differentiated by the emphasis placed by ecology on the biotic rather than the abiotic world.
 - differentiated by the lack of utility of ecology in solving world problems.
 - differentiated by the inherent focus of environmentalism on human concerns.
 - both scientific fields of inquiry that generate knowledge about the natural world but use completely different tools.
- Energy from the sun determines
 - air temperature.
 - air and wind circulation patterns.
 - ocean surface currents.
 - All of the above
 - None of the above
- The amount of solar energy that reaches a given unit of Earth's surface depends primarily on
 - the angle of the sun's rays.
 - the moisture content of the air.
 - the amount of cloud cover.
 - the strength of the winds.
 - day length.
- The marine biome can be divided into life zones because
 - the rate of photosynthesis in the oceans is low.
 - ocean currents keep organisms close to where they were born.
 - water temperature, salinity, and food supply all vary within the ocean.
 - trade winds keep warm and cold waters separate.
 - continents provide barriers to movement of planktonic life forms.
- You are choosing a location on which to grow corn (*Zea mays*) and want to minimize the amount of land you need to cultivate for maximum yield. In which biome would you locate your farm?
 - Tropical rainforest because this biome is home to tremendous plant diversity.
 - Temperate evergreen forest because some of the world's largest plants are found there.
 - Temperate grassland because the topsoil is deep and rich.
 - Arctic tundra because summer days are long and soil moisture is abundant.
 - All of these biomes are equally well suited for efficient cultivation of corn.

UNDERSTANDING & APPLYING

- The Chilean matorral is located on the west coast of South America between 32°S and 37°S. The region experiences wet, cool winters and hot, dry summers. Describe the appearance and life cycles of the seed plants you would expect to find there. How would they most likely disperse their seeds? Describe some specific adaptations you might expect to encounter in at least some of the plant species there.
- In 2008 spider expert Rudy Jocqué discovered two new species of spiders in the genus *Australutica* in South Africa. Prior to this find, the only species known in the genus were all found in Australia. One of the new species was found among the oldest rock formations in southern Africa (formed about 150 million years ago). Based on what you know about continental drift, do you think undiscovered *Australutica* species might exist anywhere else in the world? Where besides Australia and southern Africa would you look for such species?

ANALYZING & EVALUATING

- Refer to the summary chart of biome characteristics below. If mean average global temperatures increase 5°C by 2100, as predicted by some climate models, which biomes would be expected to decrease in geographic extent?

9. Today by far the greatest number of species of fruit flies (genus *Drosophila*) is found in the Hawaiian Islands. Would you conclude that the genus originated in Hawaii and spread to other regions? Under what circumstances do you think it might be accurate to conclude that a group of organisms originated in the same region where the greatest number of species live today? (Hint: Review the discussion of equid phylogeny and Figure 54.14.)

10. The map below is from a 2008 paper by H. I. McCallum and colleagues (*Ecology and Society* 13: 41–57). The paper's title is "Will Wallace's Line save Australia from avian influenza?" Based on the map and what you have learned about biogeography, how would you answer the title's question? What factor(s) do you think might be influencing the geographic spread of this disease?

CHAPTER OUTLINE

- 55.1** How Do Ecologists Measure Populations?
- 55.2** How Do Ecologists Study Population Dynamics?
- 55.3** How Do Environmental Conditions Affect Life Histories?
- 55.4** What Factors Limit Population Densities?
- 55.5** How Does Habitat Variation Affect Population Dynamics?
- 55.6** How Can We Use Ecological Principles to Manage Populations?

DURING World War II the U.S. Coast Guard established a LORAN (Long-Range Aids to Navigation) tracking station on the tiny island of St. Matthew in Alaska, an isolated and unoccupied patch of tundra more than 300 kilometers from the nearest village. As an emergency food supply for the 19 men assigned to the island in 1944, the Coast Guard brought in 29 reindeer (*Rangifer tarandus*) by barge and released them.

The reindeer thrived on the thick, lush mat of lichens that covered the island. Other than the men, the island had no reindeer predators; the only other terrestrial vertebrate occupants were Arctic foxes, one species of vole, and a few ground-nesting birds. Then the war ended and the men left the island, leaving the reindeer behind in an environment with plentiful food and no natural predators.

In 1957 David Klein, a U.S. Fish and Wildlife biologist, visited St. Matthew. He and an assistant counted more than 1,350 reindeer, most of which appeared healthy. However, they also noticed areas of overgrazed lichen. In 1963 Klein and three colleagues hitched a ride to the island on a Coast Guard cutter. This time they counted more than 6,000 reindeer, packed in at a density of 47 per square mile. The island was covered with reindeer droppings, and the animals were smaller than the ones sighted 6 years earlier.

The winter of 1963–1964 brought punishing storms, record low temperatures, and tremendous snowfalls to St. Matthew. When Klein returned in summer 1966, the island was littered with reindeer skeletons. Klein found

Reindeer Games Part of the St. Matthew reindeer herd is seen in this photograph taken in 1963, shortly before a particularly severe winter destroyed most of this isolated population. The herd had grown exponentially since being introduced to the island as a food source for a Coast Guard station during World War II.

only 42 living reindeer, 41 of which were adult females; the lone male appeared to have deformed antlers. Lichens had disappeared, replaced almost entirely by sedges and grasses, on which reindeer cannot subsist. By 1980, the reindeer too had disappeared from the island.

Introducing large mammals to small islands is inherently risky, as the experience of reindeer on St. Matthew illustrates. But such introductions do not always end in disaster. Reindeer herds introduced to the subantarctic island of South Georgia almost a century ago have persisted, and their populations appear to be stable.

Why do populations of a particular species in one place explode and crash, but in another, seemingly similar, place remain stable? That knowledge is critical for understanding why some species become pests in some places and not in others, for managing sustainable harvests of economically important species, and for designing plans for conserving endangered species.

Why did introduced reindeer populations persist on the island of South Georgia but not on the island of St. Matthew?

See answer on p. 1166.

(A) *Loxodonta africana*(C) *Apis mellifera*(B) *Camarhynchus parvulus*

55.1 How Do Ecologists Measure Populations?

Well before ecology became a distinct biological discipline, people engaged in population management. Whenever we grow crops or raise livestock, we are explicitly increasing the size of populations of domesticated plants and animals. Pest control strategies aim to reduce population sizes of organisms whose presence we consider undesirable. Game wardens, park managers, and conservation biologists aim to maintain stable populations of fish, wildlife, and threatened or endangered species. All of these activities require an understanding of **population dynamics**: the patterns and processes of change in populations. The study of population dynamics also allows us to understand the changes in populations we make inadvertently in the course of other human activities—as when the Coast Guard introduced reindeer to St. Matthew Island.

A **population** consists of the individuals of a species that interact with one another within a given area at a particular time. Populations are important units for study because groups of individuals that interact in time and space have ecological characteristics that individuals do not. At any given moment, an individual organism occupies only one point in space and is a particular age and size. The members of a population, however, are distributed over space, and they vary in age and size.

Population **density** is the number of individuals per unit of area or volume. Density is a function of processes that add individuals to the population (births and immigration) and processes that reduce the number of individuals in the population (deaths and emigration). Populations also have a characteristic **age structure**, or distribution of individuals across age

55.1 Identifying Individuals (A) The pattern of folds and notches on the ears of an elephant is distinctive and can be used to recognize individuals in a population. (B) The idea of attaching a metal band to a bird's leg to identify an individual dates back at least to 1595, when the French king Henry IV banded the royal peregrine falcons. Scientific banding for population studies, however, did not become widely established until the early years of the twentieth century. Galápagos finches such as this small tree finch have been extensively studied and marked in this way. (C) Worker bees in a hive are individually indistinguishable to ecologists, who have come up with ingenious methods of marking. This female honey bee sports a computer chip on her back, which not only identifies her but also logs her movements between the hive and flowers.

categories, and a characteristic **dispersion pattern**, or spatial distribution of individuals in the environment.

These properties of populations, which are constantly changing because of births, deaths, and movements of individuals, influence the stability of populations and affect the ways in which populations of one species interact with populations of other species. Thus, to study populations, ecologists need to count the individuals in a given area and determine their ages.

Ecologists use a variety of approaches to count and track individuals

How the individuals in a population are counted depends on the nature of the organism under study. Populations of animals are usually more challenging to count than populations of trees. Most animals can move, so to avoid double counting, individuals must be identified. Nevertheless, counting every tree in a forest can be logistically difficult, even though the trees are standing still.

In some species, individuals are large and distinct enough, and populations small enough, that investigators can identify all the individuals and count them. Biologists performed this type of count, called a **full census**, on the African elephant population of Samburu and Buffalo Springs National Reserves in Kenya. By monitoring the elephants for 21 months, the biologists learned to recognize each of the 760 individuals in the population, primarily by their unique and distinctive ear markings (**Figure 55.1A**).

For most species, however, recognizing individuals is impossible or impractical. If biologists are to identify individuals of such species, they must be marked in some way. No single form of artificial marking works for all species. Plants can be marked with tags tied to their branches or by stakes in the ground nearby. Birds can be marked by colored bands on their legs (Figure 55.1B), and butterflies and beetles with small dabs of colored paint in different patterns. Honey bees can be monitored with fully automatic radio frequency identification (RFID) technology—the same technology used for tracking supermarket purchases (Figure 55.1C). Individual bees are marked with a chip, and a reader is placed at the hive entrance to register movements of the marked bees. Small mammals can be marked by bleaching or dyeing their fur in strategic places.

In most species, populations are too large, and their individual members too small, too similar in appearance, or too mobile, for a full census to be conducted. Thus population sizes are often estimated from representative samples using statistical methods.

Ecologists can estimate population densities from samples

Ecologists usually measure the densities of terrestrial organisms as the number of individuals per unit of area. They may measure the densities of organisms living in soil, air, or water as the number or mass per unit of volume. Ecologists obtain these measurements from sample units, then extrapolate from these samples to estimate the total population density.

Estimating population densities is easiest for sessile organisms. Investigators need only count the individuals in a sample of representative locations and extrapolate the counts to the entire geographic range of the population. Individuals may be counted within marked and measured areas called **quadrats**. Plants are often counted along a **transect**—a line drawn across an area within the population's range (often designated by a string marked at regular intervals). Any individual that touches the line is counted. By making repeated counts with either of these methods, investigators can make reasonably good estimates of the size of a population.

Counting mobile organisms is more difficult because individuals move into and out of sampling areas. In such cases, investigators may use the **mark-recapture method** (Figure 55.2). They begin by capturing, marking, and then releasing a number of individuals. Later, after the marked individuals have had time to mix with unmarked individuals in the population (but before enough time has elapsed for births, deaths, and individual movement to affect the population size significantly), another sample of individuals is captured. This sample is then used to obtain an estimate of the total size of the population in the sampling area. This is done by applying the equation described in Figure 55.2, which assumes that the *proportion* of marked individuals in the second sample (i.e., individuals that

RESEARCH TOOLS

55.2 The Mark-Recapture Method The method described here is used to estimate population sizes for animal populations in which the individuals are highly mobile (such as *Ixodes scapularis*, the black-legged tick). Once a sampling area has been determined, investigators capture, mark, and then release individuals of the organism of interest. The proportion of these marked individuals that appears in a second sample is assumed to be the same as the proportion of the total individuals in that sample to the area's total population.

were captured and marked in the first sample) is about the same as the proportion of individuals in the sampling area that were captured in the first sample.

For some species, however, this assumption does not apply. Some captured animals learn to avoid traps or leave the sampling area and are thus less likely to be recaptured than are unmarked individuals. Others become “trap-happy” (some mice, for example, reenter live traps repeatedly in order to snack on the peanut butter bait). In some cases the act of marking may reduce an individual's chances of survival due to the stress of handling or inadvertent alterations of appearance that make marked individuals more conspicuous to predators. Ecologists use statistical techniques to correct for these errors and improve the accuracy of population estimates.

Determining the size and density of populations is important, but these numbers are only a starting point for understanding population dynamics because not all individuals contribute equally to population growth.

A population's age structure influences its capacity to grow

The **age structure** of a population—the distribution of individuals across age categories—has a profound effect on

WORKING WITH DATA:

Monitoring Tick Populations

Original Paper

Falco, R. C. and O. Fish. 1988. Prevalence of *Ixodes dammini* near the homes of Lyme disease patients in Westchester County, New York. *American Journal of Epidemiology* 127: 826–830.

Analyze the Data

Lyme disease is a chronic and debilitating condition caused by spirochete bacteria of the genus *Borrelia*, which infect humans by way of the bite of an intermediate host, the black-legged tick *Ixodes scapularis* (also known as the deer tick). The incidence of Lyme disease has increased dramatically in the past 20 years, particularly in the northeastern United States. In order to assess the risk of exposure to this disease in Westchester County, New York, investigators measured the abundance of deer ticks in suburban lawns near wooded areas using the mark-recapture method described in Figure 55.2. (Ticks are typically collected by dragging a white cloth along the ground; the ticks latch onto the cloth in much the same way they would to a passing leg.) By drag-sampling one representative lawn, they collected the data shown in the table.

QUESTION 1

Refer to Figure 55.2. Using the equation and other information described in that figure, estimate the total number of ticks in the sampled lawn from the data below.

QUESTION 2

The lawn was approximately 700 m² in size. What is the approximate density of ticks per square meter?

QUESTION 3

What do you think might be the implications of this study for residents of this neighborhood?

	Original capture event	Second capture event (3 weeks later)
Adult ticks captured	180	33
No. of marked ticks	180 ^a	8

^aAll ticks captured in the first event were marked with acrylic paint and released.

Go to **BioPortal** for all WORKING WITH DATA exercises

population growth because reproductive capacity varies with age. Populations with a large proportion of individuals in their peak reproductive years have a greater potential to grow than do populations dominated by individuals that are too young or too old to reproduce.

In some species, reproduction is the province of only a tiny fraction of the population for only a short interval during the life cycle. For example, adults of the tiny insect *Clunio marinus* (the “one-hour midge”) mate, lay eggs, and die within about an hour after completing their larval development. In contrast, some vertebrates, such as elephants, are capable of reproducing for years.

Consider the results of a long-term study of the age structure of the elephant population of Kidepo Valley National Park, Uganda, and how it changed over time. Relative to the population in 1970, the 2000 population had more elephants over 25 years of age (Figure 55.3). The change was the result of

years of differential mortality among young elephants due to drought, and among adult males due to ivory poaching. The age structure as of 2000 portends an increase in the population’s growth rate, given that female African elephants become fertile around age 10 to 15 and can continue producing offspring through their fifties.

A population’s dispersion pattern reflects how individuals are distributed in space

Dispersion refers to the distribution of individuals in space. Dispersion affects how individuals in a population interact with one another and thus can have important effects on population growth. In addition, ecologists must understand the dispersion patterns of a species to choose appropriate sampling areas and statistical methods for estimating population sizes.

Ecologists recognize three basic dispersion patterns:

Go to Animated Tutorial 55.1
Age Structure and Survivorship
Life10e.com/at55.1

55.3 Changes in Age Structure Influence Population Growth

The elephant population in Kidepo Valley National Park, Uganda, was monitored between 1970 and 2000. During this time, the proportion of the population in the prime reproductive age range (15–30 years) grew considerably. Such an age structure in a population is likely to result in a high rate of growth.

Loxodonta africana

(A) Clumped dispersion

*Orcinus orca*

(B) Regular dispersion

*Morus bassanus*

(C) Random dispersion

*Taraxacum officinale*

55.4 Dispersion Patterns (A) Orcas hunting together in pods display a clumped dispersion pattern. (B) Nesting seabirds often stake out territories with a radius defined by their wingspans—an amount of space they can defend without leaving the nest. This behavior results in a regular dispersion pattern. (C) Dandelion seeds are dispersed by the wind in random fashion, so the plants that grow from those seeds show a random dispersion pattern.

- A **clumped dispersion pattern** occurs when the presence of one individual at any point in space increases the probability of others being near that point (**Figure 55.4A**).
- A **regular dispersion pattern** occurs when the presence of one individual at any point in space reduces the probability of others being near that point (**Figure 55.4B**).
- A **random dispersion pattern** occurs when the presence of one individual at any point in space does not affect the probability of other individuals being near that point (**Figure 55.4C**).

Dispersion patterns can vary among species, or among populations within species. Spatial variation in environmental conditions strongly influences dispersion patterns. Small-scale differences in temperature, humidity, or wind speed can make particular places more or less suitable for certain organisms. Aphids, for example, cluster along the protruding veins of leaves, where they are sheltered from wind. Interactions among individuals may also bring about characteristic dispersion patterns. Social life, with the cooperation it involves, tends to promote clumped dispersion patterns. By contrast, intraspecific competition for food, space, or mates tends to space individuals apart in regular dispersion patterns.

RECAP 55.1

To understand the dynamics of populations, ecologists measure their density, age structure, and dispersion patterns.

- What are some of the ways in which population density can be measured? **See p. 1151**
- How can the age structure of a population influence its growth? **See pp. 1151–1152 and Figure 55.3**
- How do environmental factors influence dispersion patterns? **See p. 1153 and Figure 55.4**

Once the sizes, densities, and other important traits of populations have been measured, these data can be used to describe various “survival strategies” found among populations and to understand and predict changes within and among populations.

55.2**How Do Ecologists Study Population Dynamics?**

Quantifying population density and age structure provides useful information about populations, but those traits alone cannot explain how, when, and why populations change in size. In order to understand population growth, ecologists must measure population *processes* as well as population traits. The study of population processes is known as **demography**.

Demographic events determine the size of a population

The size of a population changes over time because of **demographic events**: births, deaths, immigration, and emigration. Over any given interval of time, the size of a population increases by the number of individuals added to the population by births and by immigration (the movement of individuals into the population from elsewhere) and decreases by the number of individuals lost from the population by deaths and by emigration (individuals leaving the population to go elsewhere). This relationship is expressed mathematically as

$$N_1 = N_0 + (B - D) + (I - E) \quad (55.1)$$

where

N_1 = the number of individuals at time 1

N_0 = the number of individuals at time 0

- B = the number of individuals born between time 0 and time 1
- D = the number that died between time 0 and time 1
- I = the number that immigrated between time 0 and time 1
- E = the number that emigrated between time 0 and time 1

Using Equation 55.1 to estimate N_1 over multiple time intervals helps researchers estimate the *rate of change in population size over time*—that is, the growth rate of the population.

Life tables track demographic events

The study of population dynamics requires keeping track of demographic events in populations and determining the rate (number per unit of time) at which they occur. An individual is born only once and dies only once; birth rates and death rates are properties of populations. A **life table** is a tool that ecologists use for these purposes. Life insurance companies use similar tables (called actuarial tables) to determine how much to charge people of different ages for insurance policies. Data from life tables can be used to identify the principal mortality factors, or causes of death, at particular life stages, to predict future population trends, and to develop strategies for managing populations of species of commercial or ecological value.

COHORT LIFE TABLES Life tables can be constructed by a number of methods. To construct a cohort life table, investigators start with a **cohort**—a group of individuals born within the same time frame, or age class—and record their deaths until no individuals from the cohort remain alive. This type of life table is sometimes called a horizontal life table because it is based on data collected *across* the entire life span.

The age classes used in a cohort life table depend on the life cycle of the organism of interest. Age-dependent cohort life tables track demographic events as a function of calendar age. Stage-dependent cohort life tables track demographic events at various stages of the life cycle (e.g., eggs, larvae, pupae, and adults in insects). They are commonly used when survival and reproduction depend more on developmental stage than on calendar age, as is the case, for example, with insects and other animals that undergo metamorphosis.

Using the data in a cohort life table, investigators can calculate **mortality**: the proportion of individuals of each age class that die before reaching the next age class. By following a cohort, investigators can also calculate the average individual’s chance of dying during a particular time interval, a value known as the per capita death rate, or d . By the same token, they can calculate **survivorship** (represented by the term l_x), which is the likelihood of an individual member of the cohort surviving to reach age x (Table 55.1).

ESTIMATING REPRODUCTIVE CAPACITY A cohort life table can also be used to track the degree to which individuals in different age categories contribute to reproduction (and hence population growth). Investigators can use the data in the table to calculate the number of offspring the average individual produces, or the per capita birth rate, b . Because only females produce offspring, life tables generally track the number of female offspring produced by each female during each time period—a factor called **fecundity** (indicated by the term m_x). The portion of the life table that tracks fecundity is called a fecundity schedule (see Table 55.1, rightmost column). Such data allow scientists to estimate a population’s potential for growth.

The data in Table 55.1 track the survivorship (l_x) and fecundity (m_x), respectively, of a cohort of the cactus finch species *Geospiza scandens* on Isla Daphne in the Galápagos. Peter and Rosemary Grant followed a cohort of 210 birds from the time they hatched in 1978 until 1991, at which time only 3 individuals—all males—remained alive. All of the cactus finches on the island were banded so that the Grants could recognize them as individuals (see Figure 55.1B).

The *G. scandens* life table shows that mortality was high during the first year of life, then dropped dramatically for several years before increasing in later years. The fecundity data indicate that females may begin breeding as young as 1 year of age and may continue breeding throughout their lives.

Survival and breeding success, however, are not correlated exclusively with age. Other observations of conditions on Isla Daphne revealed a correlation of fecundity with rainfall, which

TABLE 55.1 Life Table for the 1978 Cohort of *Geospiza scandens* on Isla Daphne

Age Class (years)	Number Alive	Survivorship ^a	Mortality ^b	Fecundity ^c
0–1	210	—	0.57	0.00
1–2	91	0.43	0.14	0.05
2–3	78	0.37	0.10	0.67
3–4	70	0.33	0.07	1.50
4–5	65	0.31	0.05	0.66
Increased rain				
5–6	62	0.30	0.32	5.50
6–7	42	0.20	0.45	0.69
Drought				
7–8	23	0.11	0.35	0.00
8–9	15	0.07	0.07	0.00
9–10	14	0.07	0.21	2.20
10–11	11	0.05	0.09	0.00
11–12	10	0.05	0.60	0.00
12–13	4	0.02	0.25	—
13	3	0.01	—	—

^a Survivorship (l_x) = the proportion of the original cohort (here, of 210 individuals) who survive to age x .
^b Mortality (d) = the proportion of individuals of age x who die before reaching age $x + 1$.
^c Fecundity (m_x) = number of fledgling females per female per breeding season. Of the 210 birds in this cohort, 90 were females.

55.5 Survivorship Curves Ecologists recognize three general types of survivorship curves. Notice that the number of survivors has been plotted on a logarithmic scale. Three species provide real-world examples of the three types of life histories.

in the Galápagos varies dramatically from year to year. This life table and other ecological data, taken together, suggest that the survival of adult birds and the number of offspring they are able to fledge depend on food availability—that is, on cactus flower and fruit production, which is strongly correlated with rainfall (see Table 55.1). In short, life table data can be useful in identifying the ecological factors that affect population dynamics, at least over the short term.

Fecundity schedules vary greatly among species not only because organisms differ in the number of offspring they can produce, but also because they vary in the timing of reproduction. Whereas female *G. scandens* can begin breeding at the age of 1 year and in favorable conditions may fledge multiple broods each season, African elephant females do not produce offspring until they are at least 15 years old and usually produce only one calf every 5 years or so.

VERTICAL LIFE TABLES Because not all species can be easily followed over time, some life tables are constructed by sampling a population at a single time. These life tables cut across all age categories and thus are known as **vertical life tables**. One way to construct a vertical life table is to record information from a death assemblage, a collection of bodies or fossils of individuals that lived together in a particular place at a given time. Similarly, the birth and death dates on tombstones in a cemetery, for example, can be used to construct a vertical life table for a human population and to estimate its probability of reaching different ages.

Survivorship curves reflect life history strategies

The construction of life tables has allowed ecologists to observe common life history patterns, reflecting common solutions to ecological challenges, across a tremendous diversity of organisms. For example, the proportions of individuals surviving through each life stage (survivorship, l_x) can be taken from a life table and plotted graphically to construct a **survivorship**

curve. Typically, a survivorship curve is constructed for a hypothetical cohort, usually of 1,000 individuals, by plotting the numbers of individuals expected to survive to reach each age category on a logarithmic scale.

Ecologists have noticed that survivorship curves tend to take one of three general shapes:

- Species with **physiological survivorship curves** experience high overall survivorship through adulthood but steep declines late in life (the graphic representation is concave; **Figure 55.5A**). Species with this type of survivorship curve (such as humans, elephants, and many other large mammals) typically have low fecundity but provide parental care to their offspring, which reduces the risk of death in early stages of development.

- Species with **ecological survivorship curves** are faced with a constant risk of mortality at all ages (the graphic representation is linear; **Figure 55.5B**). Many bird species display this pattern.
- Species with **maturational survivorship curves** experience low survivorship early in life and higher survivorship once they reach maturity (the graphic representation is convex; **Figure 55.5C**). Species with this type of survivorship curve (such as most insects, marine invertebrates, and annual plants) tend to produce many offspring but provide little or no parental care.

These different survivorship curves reflect differences in the ways in which organisms partition their time and energy among growth, maintenance, and reproduction; the way a species partitions its energetic resources is referred to as its **life history strategy**. Understanding the risks organisms face during different stages of their lives helps clarify why life histories differ among species. Although these basic strategies are to a large degree genetically and taxonomically determined, varying environmental conditions can influence life history traits. Witness how, for example, the number of offspring produced by cactus ground finches in a year depends on cactus flower and fruit availability, which in turn depends on the availability of rainfall.

RECAP 55.2

Life tables can be constructed either by following a cohort of individuals through time or by recording age at death in a vertical life table. Survivorship curves can be constructed by plotting the likelihood of survival to different ages. Differences in the shape of these curves can shed light on differences in life history strategies.

- What kinds of information does a life table provide about a population? **See pp. 1154–1155 and Table 55.1**
- What are the differences between a vertical and a cohort life table? **See pp. 1154–1155**
- Describe the three types of survivorship curves. **See pp. 1155–1156 and Figure 55.5**

Environmental variation influences survivorship and fecundity. Comparisons across populations and species reveal different patterns in life history traits, which allow organisms to cope with different environmental challenges.

55.3

How Do Environmental Conditions Affect Life Histories?

Because resources and mortality factors vary greatly among environments, life history strategies also vary dramatically. Those variations, in turn, determine how fast populations can grow.

Survivorship and fecundity determine a population's growth rate

To see how a population is likely to grow, ecologists can use life table data to calculate the population's **per capita growth rate**, symbolized r . A population's growth rate is the difference

between the per capita birth rate (b) and the per capita death rate (d) (leaving aside, for the moment, immigration and emigration). In other words, it is the average rate of change in population size per individual per unit of time. It is expressed by the equation

$$r = b - d \quad (55.2)$$

If the per capita birth rate is greater than the per capita death rate, then $r > 0$ and the population is growing. If the per capita death rate is greater than the per capita birth rate, then $r < 0$ and the population is declining. The equilibrium state, $r = 0$, would indicate a stable population that is neither growing nor declining.

The maximum value of r (r_{\max}) is referred to as the population's **intrinsic rate of increase**. It reflects the rate of increase that is inherent in the organism under ideal conditions—that is, independent of any external (environmental) constraints on population growth. A population can reach r_{\max} only for a limited time, if at all, since environmental constraints almost always exist.

Life history traits vary with environmental conditions

Birth rates and death rates are both influenced by environmental factors, so r changes as the environment changes. The life history traits most influenced by environmental conditions include:

- age at first reproduction (generation time)
- number of broods per female (the number of times a female produces offspring)
- number of offspring per brood (the number of offspring produced each time a female reproduces)

These traits vary not only between species, but also between populations of the same species.

Opportunities for reproduction for some species are limited to certain locations or certain times of year, whereas other species and populations can breed continuously over their life span. Many desert wildflowers grow and flower only during the spring rainy season, and they may not be able to reproduce at all in years when rainfall is inadequate. In contrast, some tropical vines flower continuously in their warm, moist rainforest environment.

Species that can reproduce multiple times over the course of their adult lives are **iteroparous** (*itero*, “repeat”; *pario*, “beget”). **Semelparous** species (*semel*, “once”) reproduce only once (**Figure 55.6**). Generally speaking, semelparous species produce many more offspring in a single brood than iteroparous species do over their entire lifetimes; semelparity is thus sometimes referred to as “big bang” reproduction.

Semelparity is typical of organisms that experience no great survival advantage upon reaching adulthood; it includes some fishes, many insects, and all annual plants. In contrast, iteroparity is typical of organisms whose survival chances increase once they reach maturity. For example, because environmental conditions within the nests of social insects such as honey bees and ants are remarkably stable, iteroparity is the rule among these species; some queens live 10 years or longer and reproduce over their entire adult lives.

Orgyia antiqua

55.6 Big Bang Reproduction Semelparous species reproduce only once and invest a great deal of energy in producing the maximum number of offspring. Female rusty tussock moths do not fly but remain with their empty cocoons, which are attached to the plants that are the caterpillar-stage food source. The stationary female lays a large number of eggs and then dies. When the eggs hatch the following spring, the larvae are surrounded by foliage they can eat.

Life history traits are influenced by interspecific interactions

Predation and other interactions among species can influence life history strategies in many ways. Some populations of guppies (*Poecilia reticulata*) in Trinidad, for example, live in streams where they are attacked and eaten by larger fish. But some streams have waterfalls that predatory fishes are unable to negotiate. Guppies that live in the predator-free areas upstream from those waterfalls have lower death rates than guppies below the falls. To see whether the risk of being eaten by a predator influenced the life history strategies of these guppies, David Reznick and his colleagues collected guppies from high-predation and low-predation sites and raised them in the laboratory. Some guppies from each group were provided with plentiful food, and others with limited food, to simulate the variation the fish would typically encounter in their home streams. In the laboratory, where no predators were present, guppies from high-predation sites matured earlier, reproduced more frequently, and produced more offspring in each brood than did guppies from low-predation sites, no matter how much food they received. The investigators concluded that predation had selected for early and frequent reproduction.

RECAP 55.3

The difference between birth rate and death rate provides an estimate of a population's per capita growth rate, or r . That rate is strongly influenced by the population's life history strategy, which in turn is highly dependent on environmental conditions.

- Give some examples of life history traits that vary with environmental conditions. [See p. 1156](#)
- Explain the difference between iteroparity and semelparity. [See p. 1156](#)
- How can predation affect the evolution of life history strategies? [See p. 1157](#)

In any given species, environmental factors may influence the growth of populations differently in different places and at different times.

55.4 What Factors Limit Population Densities?

What would happen if all the offspring produced by a population survived to reproduce themselves? The prospects are alarming. In 1911, L. O. Howard, then chief entomologist of the U.S. Department of Agriculture, estimated that, if all their offspring were to survive, a pair of flies beginning to reproduce on April 15 would produce a population of 5,598,720,000,000 adults by September 10 of the same year. Other entomologists took issue with Howard's calculation—they pegged the number much *higher*. Given such amazing reproductive capacities, it is clear there are forces at work that limit the growth of fly populations (and populations of every other organism).

All populations have the potential for exponential growth

As the number of individuals in a population increases, the number of reproducing individuals also increases, so the number of new individuals added per unit of time accelerates, even though the per capita rate of increase remains constant. If births and deaths occur continuously at constant rates, a graph of the population size over time forms a continuous upward curve (**Figure 55.7**). This pattern is known as **exponential growth**. Mathematically, the change in the number of individuals N over an interval of time T can be expressed as $\Delta N / \Delta T$ where Δ is the mathematical representation for "change in." The ratio between N and T can be expressed as the average contribution of each individual to population growth r (remember from Equation 55.2 that $r = b - d$) multiplied by the number of individuals in the population. In mathematical terms,

$$\frac{\Delta N}{\Delta T} = rN$$

Using the notation of differential calculus, which in this case simply indicates that the time interval represented by Δ is short, this equation can be expressed as

$$\frac{dN}{dT} = rN \quad (55.3)$$

55.7 Exponential Population Growth Can Lead to a Population Crash The reindeer herd introduced on St. Matthew Island experienced favorable conditions and grew exponentially for many years. A single catastrophically cold winter triggered a population crash that eventually resulted in the death of the entire population.

 **Go to Animated Tutorial 55.2**
Exponential Population Growth
Life10e.com/at55.2

The term dN/dT is the rate of change in the size of the population over time, and the expression rN is sometimes called the **biotic potential** of the population.

Some populations may grow at rates close to their biotic potential, but only for short periods. During the 20 years following their introduction, the reindeer population described at the opening of this chapter grew exponentially, as seen in Figure 55.7. When the herd was first introduced, it had ample habitat, abundant food, and no predators, so there was nothing to limit the population's growth. Favorable climate conditions also allowed the population to grow exponentially. A sudden change in climate conditions—deep snow that made foraging difficult—was a major factor leading to the population's crash. Although the crash was precipitated by unusually harsh weather conditions, the relatively poor physical condition of the reindeer in the herd, caused by overcrowding and overgrazing of the lichens that were their principal food source, contributed to the massive mortality.

 **Go to Media Clip 55.1**
The Biotic Potential of a Population
Life10e.com/mc55.1

Logistic growth occurs as a population approaches its carrying capacity

No real population can maintain exponential growth for very long. As a population increases in density, the resources it requires—such as food, nest sites, and shelter—become depleted. In the absence of adequate resources to sustain more individuals, birth rates drop and death rates rise.

Any given environment has only enough resources to support a finite number of individuals of a species indefinitely.

55.8 Logistic Population Growth Levels Off In an environment with limited resources, a population typically stops growing exponentially before it reaches the environmental carrying capacity (K). The data here were recorded from a laboratory population of sawtoothed grain beetles maintained on a constant food supply; it is a typical logistic growth pattern, which forms an S-shaped curve.

 **Go to Animated Tutorial 55.3**
Logistic Population Growth
Life10e.com/at55.3

That number of individuals, referred to as the environment's **carrying capacity** (K), is a function of its resources. The growth of a population typically slows down as its density approaches the environmental carrying capacity. A population that exhibits decreasing growth as resources become more scarce displays a pattern called **logistic growth**, in which a graph of population size over time forms an S-shaped curve. **Figure 55.8** shows this growth pattern in a laboratory population of beetles maintained on a constant food supply.

To generate the S-shaped logistic growth curve from the equation for exponential growth we add a term,

$$\frac{K - N}{K}$$

This quantity represents the reduction in population growth caused by preemption of available resources and is referred to as **environmental resistance**. As long as the population size is less than the carrying capacity (i.e., $N < K$), only a fraction of the available resources are being used. As the population size approaches the carrying capacity, however, the fraction of resources available for any new individual becomes smaller. The implication is that each individual added to the population depresses population growth by an equal amount. Thus

$$\text{rate of change in population size over time} = \text{biotic potential} \times \text{environmental resistance}$$

or, in mathematical terms,

$$\frac{dN}{dT} = rN \times \frac{K - N}{K} \quad (55.4)$$

Population growth should stop when $N = K$ because at that point, $K - N = 0$, so $(K - N)/K = 0$, and thus $dN/dT = 0$ and the population remains at a constant size.

Life10e.com/ac55.1

r-strategists**HABITAT**

Can inhabit a broad range of habitats. High tolerance for both environmental instability and low-quality resources.

PHYSIOLOGY

Rapid embryonic development, rapid maturation to reproductive age, small body size.

REPRODUCTIVE STRATEGY

Random mating. Reproduce once (semelparity) resulting in a large number of offspring. Little or no parental investment in each offspring.

SURVIVORSHIP

Short life span, density-independent mortality, typically a maturational survivorship curve (see Figure 55.4).

POPULATION FLUCTUATION

Short periods of exponential population growth followed by periodic or seasonal population crashes.

EXAMPLES

Dandelions, house flies, rabbits

K-strategists**HABITAT**

Specific habitat requirements, including environmental stability. Efficient users of specific and usually high-quality resources.

PHYSIOLOGY

Extended embryonic development, long maturation to reproductive age, large body size.

REPRODUCTIVE STRATEGY

Mate choice, pair bonds. Reproduce many times (iteroparity), each event producing few offspring. Large parental investment in each offspring.

SURVIVORSHIP

Long life span, density-dependent mortality, typically physiological or ecological survivorship curve (see Figure 55.4).

POPULATION FLUCTUATION

Slowly rising population growth that stabilizes and levels off at carrying capacity (K).

EXAMPLES

Oak trees, bluebirds, polar bears

55.9 Two Life History Strategies Species whose life histories are geared to achieve the maximum possible rate of population increase are referred to as *r*-strategists; those whose population dynamics are bounded by carrying capacity are *K*-strategists. The life histories of most species combine elements of both strategies.

Different population regulation factors lead to different life history strategies

Species vary in their capacity to reproduce, as well as in the extent to which they are vulnerable to density-dependent and density-independent mortality factors. Some of this variation in life history traits appears to result from adaptation to different habitat conditions. Generally, unpredictable habitats are associated with high fecundity and correspondingly high intrinsic rates of increase as organisms make the most of rare opportunities to reproduce. Conversely, predictable habitats, where organisms have a high probability of reproductive success, are associated with low fecundity and low r .

Species whose life history strategies allow for high intrinsic rates of increase are called ***r*-strategists**, and species whose life history strategies allow them to persist at or near the carrying capacity (K) of their environment are called ***K*-strategists** (Figure 55.9). Keep in mind, however, that these categories are not absolute; many species fall along a continuum between these two strategies.

For *r*-strategists, life is uncertain. Individuals tend to reproduce only once and to produce large numbers of offspring. They can generally use a wide variety of resources and tolerate a wide range of conditions. *K*-strategists are adapted to predictable environments, are long-lived, and reproduce several times; their smaller numbers of offspring have a high probability of surviving to adulthood. *K*-strategists tend to be more specialized in their resource use and less tolerant of variation in resource quality.

That life history strategies can evolve is suggested by genetic correlations among suites of life history traits. Such genetic correlations imply either simultaneous selection on two or more life history traits or linkages among the genes that code for those traits. Across *Drosophila melanogaster* strains, for example, a high intrinsic rate of increase is correlated with the ability to reproduce under starvation conditions and with the ability to develop on a variety of media in the laboratory—both of which are consistent with the *r* strategy of tolerating a wide range of resources and conditions.

Several ecological factors explain species' characteristic population densities

Density-dependent and density-independent factors can explain how populations grow or decline, but they do not explain why

Population growth can be limited by density-dependent or density-independent factors

When resources are limited, adding more individuals to a population risks making things worse for everyone. Factors with an effect on population size that increases in proportion to population density are called **density-dependent** regulation factors. These factors include the following:

- **Food supply.** As a population increases, it may deplete its food supply, reducing the amount of food available to each individual. Poor nutrition may then increase the death rate or decrease the birth rate.
- **Predators** may be attracted to areas with high densities of their prey. If predators capture a larger proportion of the prey population than they did when that population was small, the death rate of the prey population rises.
- **Pathogens** may spread more easily in dense populations than in populations with fewer individuals per unit of area, resulting in a rise in the death rate.

Not all factors that change population size act in a density-dependent manner, however. A period of extreme cold, or an exceptionally strong hurricane, may kill a large proportion of the individuals in a population regardless of the population's density; such an event is **density-independent**. Abiotic factors tend to act in a density-independent manner, whereas biotic factors (such as food supply) tend to be density-dependent. For an ecological process to regulate population size (i.e., to maintain the population at a certain level), it must exhibit density dependence such that some sort of negative feedback is applied when populations increase.

55.10 Newly Introduced Populations Can Grow Rapidly Between 1988 and 2009, the range of zebra mussels in eastern North America increased exponentially, through rapid population growth as well as by inadvertent transport on barges moving among waterways. Female mussels can lay more than 1 million eggs in a single season, and in North America the species has few natural predators. Humans can unwittingly transport zebra mussel larvae from one body of water to another on their fishing boats and other watercraft, and in recent years the invasive pest has begun to appear in lakes and streams of the American West.

some species are common whereas others are rare—that is, why the characteristic densities of species differ. Many factors explain why typical population densities vary so greatly among species, but three of these factors are especially influential:

- *Species that use abundant resources generally reach higher population densities than species that use scarce resources.* Thus, on average, the fruit fly *Drosophila melanogaster*, which feeds on yeasts and other microbes found on just about any kind of rotten fruit, reaches substantially higher population densities than do other fruit fly species that feed on the microbes found on specific fruits.
- *Species with small body sizes generally reach higher population densities than species with large body sizes.* In general, population density decreases as body size increases because, on a per capita basis, small individuals require less energy to survive than large individuals.
- *Complex social organization may facilitate high population densities.* Highly social species, including ants, termites, and humans, can achieve remarkably high population densities.

Some newly introduced species reach high population densities

Species that are introduced into a new region, where their normal predators and pathogens are absent, sometimes reach

population densities much higher than those in their native ranges. Sometimes these high population densities are only temporary; these densities decline if and when new mortality factors exert an influence. In the absence of such factors, however, populations in the newly colonized habitat may remain so dense that the introduced species becomes a major problem for native species.

The population of zebra mussels (*Dreissena polymorpha*) in North America demonstrates the speed with which newly introduced populations can grow. Zebra mussels first appeared in Lake St. Clair, between Lake Erie and Lake Huron, in 1988. They were probably transported there from Europe in the ballast water of transoceanic cargo ships. They spread rapidly and today occupy most of the Great Lakes and the Mississippi River drainage (**Figure 55.10**), reaching densities as high as 400,000 individuals per square meter in some places. Because they attach to any stable underwater substrate, zebra mussels can cover the bottoms of boats and clog municipal water supply intakes and power plant pipelines. They even settle on other aquatic organisms, causing problems for native mussels. Such high densities are never found in their native Europe, where more than 100 species of predators and parasites keep zebra mussel population densities under control.

Evolutionary history may explain species abundances

The three key factors that explain variation in population densities cannot explain all differences in species abundance. For example, although Douglas firs (*Pseudotsuga menziesii*) and giant sequoias (*Sequoiadendron giganteum*) are both large trees that use the same sources of energy (sunlight) and nutrients (soil), Douglas firs are abundant throughout western North America, whereas giant sequoias are restricted to a few groves in the Sierra Nevada. Similarly, each of several species of desert pupfish (genus *Cyprinodon*) is restricted to a single spring in Death Valley, California, whereas smallmouth bass (*Micropterus dolomieu*) can be found in many of the rivers and lakes of eastern North America. To explain these differences, it is important to know not just the contemporary ecology of these organisms, but also their evolutionary history.

As Chapter 23 described, a new species can originate in several ways. Species that arise by polyploidy or by founder events inevitably begin with a very small, local population. Desert pupfish species appear to have evolved in isolation as increasing aridity in Death Valley over the past 50,000 years cut once continuous populations off from one another. Conversely, when a species is declining toward extinction (as may be happening to the giant sequoia), its range shrinks until it vanishes when the last individual dies.

RECAP 55.4

Population sizes are limited by the carrying capacity of the environment, which is determined by the availability of resources. Species associated with unpredictable habitats tend to be *r*-strategists, whereas species associated with predictable habitats tend to be *K*-strategists.

- Why can populations grow exponentially only for short periods? **See pp. 1157–1158 and Figures 55.7 and 55.8**
- What is the difference between density-dependent and density-independent factors that influence populations size? **See p. 1159**
- Describe the characteristics of *r*-strategists and *K*-strategists. **See p. 1159 and Figure 55.9**

A species is rarely found in all of the habitats that seem suitable for it. Geological history and the evolutionary histories of species supply one type of explanation for this observation (see Section 54.5). This chapter next explores another area of explanation: spatial variation in habitat suitability.

55.5

How Does Habitat Variation Affect Population Dynamics?

Most natural history field guides have maps showing the geographic range over which a species can be found. But not even the most abundant species is found everywhere within its mapped range. Every species has particular habitat requirements that determine where within its potential range it will occur.

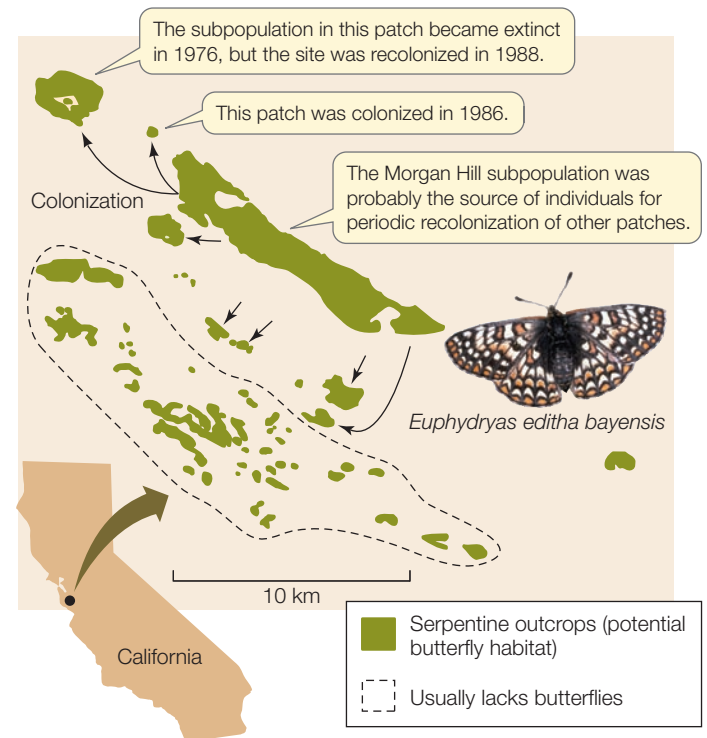

Many populations live in separated habitat patches

Most organisms live in distinct **habitat patches**, areas of a particular habitat type surrounded by areas of less suitable habitat. For example, caterpillars of the Bay checkerspot butterfly (*Euphydryas editha bayensis*) feed on only two species of annual plants (California plantain and purple owl's clover) that grow only on outcrops of serpentine rock on hills south of San Francisco, California. The butterflies are restricted to patches of these plants and cannot establish populations in the surrounding habitats that lack them.

Some populations living in separated habitat patches are effectively divided into discrete **subpopulations** that are linked together by regular movement of individuals between patches. The larger population that includes all such subpopulations is known as a **metapopulation**. Each subpopulation has a probability of “birth” (colonization of its habitat patch) and “death” (extinction in that patch). Each subpopulation grows in the ways we have described, but because the subpopulations are much smaller than the metapopulation, local disturbances and random fluctuations in numbers of individuals are more likely to cause the extinction of a subpopulation than of the entire metapopulation, as we will explain in Chapter 59. However, if individuals move frequently between subpopulations, immigration may prevent declining subpopulations from becoming extinct, a process called the **rescue effect**.

The Bay checkerspot butterfly provides a dramatic illustration of the dynamics of metapopulations. In 1960 Paul Ehrlich and his colleagues at Stanford University began studying a population of this butterfly in the Jasper Ridge Biological Preserve near the Stanford campus. They determined that the Jasper Ridge population was actually one of several subpopulations within a large, very fragmented metapopulation. They followed the Jasper Ridge subpopulation, as well as several other subpopulations within this metapopulation, over a number of years and found that the subpopulations varied enormously and asynchronously in size. Larval survival depended on climate factors (particularly temperature), the timing of rainfall, and host plant survival.

During drought years, most host plants died early in spring, before the caterpillars had developed enough to enter their summer resting stage. A severe drought in 1975–1977 led to extinctions of some of the subpopulations. One of the empty patches was repopulated a few years later, most likely by individuals from the largest single subpopulation, Morgan Hill, which as late as 1989 contained several hundred thousand butterflies (**Figure 55.11**). In 1998, however, the Morgan Hill subpopulation, which had historically been the largest in the metapopulation, went extinct. Ehrlich and his colleagues examined 70 years of climate data for the region and concluded that increasing climate variation accounted for the extinction.

55.11 A Checkerboard of Checkerspots The Bay checkerspot butterfly metapopulation is divided into several subpopulations confined to patches of habitat (serpentine rock outcrops) that contain the species' food plants.

Without a large, stable source subpopulation to provide emigrants for recolonization, as the Morgan Hill subpopulation did during the 1970s drought, it is unlikely that any of the other subpopulations will persist without human intervention.

Corridors may allow subpopulations to persist

In any metapopulation, habitat between patches through which organisms can move, known as **corridors**, plays a critical role in facilitating dispersal to maintain subpopulations. What constitutes a corridor depends on the dispersal ability of the organism. Studying corridors is experimentally daunting because long distances may separate patches; moreover, movements of animals, particularly those that fly, can be difficult to monitor. Therefore one of the first tests of the importance of corridors was a small-scale manipulative experiment using mosses growing on rocks, which provide habitat for several small arthropod species, including springtails (minute wingless hexapods) and mites.

The investigators created patches of habitat by clearing away the mosses surrounding the patches (**Figure 55.12**). In small, completely isolated patches, the number of small arthropod species present declined about 40 percent within 6 months. The investigators also created patches that were connected by narrow corridors of moss. In some cases the corridors were left intact; in others, “pseudocorridors” were disrupted by a barrier 2 cm wide. A 2-cm barrier may seem small, but it presents a daunting obstacle to arthropods only 2 mm wide. Six months later, patches connected by unbroken corridors contained more small arthropod species than did patches connected by the disrupted pseudocorridors.

Habitat Fragmentation
[Life10e.com/at55.4](https://www.life10e.com/at55.4)

A larger scale study of the effects of corridors was conducted in Palenque National Park in Mexico. Although about one-third of the park comprises tropical rainforest, that forest is surrounded by a patchwork of cattle pasture, river habitat, and forest fragments. Investigators moved individual birds, representing a wide range of species, from one patch of forest in the park to another. Some individuals were moved between forest patches that were in close proximity but were not connected by forest corridors (i.e., they were completely surrounded by cattle pastures). The rest were moved between patches that were in close proximity and surrounded by cattle pastures, but were physically connected

INVESTIGATINGLIFE

55.12 Corridors Can Rescue Some Populations Data from the experiments by Andrew Gonzales and Enrique Chaneton summarized here suggest that corridors between patches of habitat increase the chances of recolonization, and thus of subpopulation persistence.^a

HYPOTHESIS Subpopulations of a fragmented metapopulation are more likely to persist if there is no barrier to recolonization.

Method

1. On replicate moss-covered boulders, scrape off the continuous cover of moss to create a “landscape” of moss “mainland” with patches surrounded by bare rock. A central 50 cm × 50 cm moss “mainland” (M) is surrounded by 12 circular patches of moss, each 10 cm² (subpopulations). In the “insular” treatment (I), the patches are surrounded by bare rock (which is inhospitable to moss-dwelling small arthropods, and thus a barrier to recolonization). In the “corridor” treatment (C), the patches are connected to the mainland by a 7 × 2 cm strip of live moss. In the “broken-corridor” treatment (B), the configuration is the same as the “corridor” treatment, except that the moss strip is cut by a 2-cm strip of bare rock.

2. After 6 months, determine the number of small arthropod species present in each of the mainlands and small patches.

Results

Patches connected to the mainland by corridors retained as many species as did the mainland to which they were connected. Fewer species remained in the broken-corridor and insular treatments.

CONCLUSION Barriers to recolonization reduce the number of subpopulations that persist in a metapopulation.

by narrow corridors of forest habitat. The investigators then monitored the return of the captured birds to their home forest patches. Across all species, birds were more than six times more likely to be recaptured in home forest patches connected by corridors to the patches where they were released than in home forest patches that were unconnected to the patches where they were released. Even narrow forest corridors may be beneficial to tropical forest birds, which experience an increased risk of predation and greater physiological stress when they have to fly across open areas.

RECAP 55.5

A metapopulation consists of separate subpopulations living in distinct habitat patches. Corridors that facilitate movement between patches increase the chances of subpopulation persistence.

- What effects do patches of unsuitable habitat have on population structure? **See p. 1161 and Figure 55.11**
- What effects do corridors between habitat patches have on subpopulations? **See p. 1162 and Figure 55.12**

For many centuries, people have tried to reduce populations of species they consider undesirable and maintain or increase populations of desirable or useful species. Such efforts to manage populations are more likely to be successful if they are based on knowledge of how those populations grow and what determines their densities.

55.6 How Can We Use Ecological Principles to Manage Populations?

If we wish to manage other species—that is, to increase or decrease their populations—we need to understand their life histories and the dynamics of their populations. The principles of population dynamics can also help us understand the effects our own population and its activities are having on other species.

Management plans must take life history strategies into account

Knowing the life history strategy of a species can be helpful in managing populations of commercial value. The black rockfish (*Sebastes melanops*), an important game fish that lives off the Pacific coast of North America, provides one such example. Rockfish have an indeterminate growth pattern—they continue to grow throughout their lives. As in many other animals, the number of eggs a female rockfish produces is proportional to her size, so larger females produce more eggs than smaller females. In addition, older, larger females are better able to provision the eggs they produce with oil droplets, which provide energy to the newly hatched larvae, giving them a head start in life (**Figure 55.13**). Larvae from eggs with larger oil droplets, produced by larger females, grow faster and survive better than do larvae from eggs with smaller oil droplets.

These life history traits have important implications for the management of rockfish populations. Because fishermen prefer to catch big fish, intensive fishing off the Oregon coast from 1996 to 1999 reduced the average age of female rockfish from 9.5 to 6.5 years. Thus the females reproducing in 1999 were, on average, smaller than the females reproducing in 1996. This change decreased the average number of eggs produced by females and reduced the average growth rate of larvae by about 50 percent. This reduction in reproductive ability was linked to a decrease in the ability of the rockfish population to recover from intensive fishing. Maintaining productive populations of rockfish may require setting aside no-fishing zones where some females can be protected from fishing and allowed to grow to large sizes.

(A) *Sebastes melanops*

(B)

Oil droplet

55.13 Energy Stocks Give Rockfish a Head Start (A) Among rockfish, older, larger females are more reproductively successful, producing both more eggs and eggs with larger nutritive oil droplets. (B) The oil droplet attached to this rockfish larva provides it with nutrition to fuel its growth until it can feed on its own.

Management plans must be guided by the principles of population dynamics

If we look at a logistic growth curve (see Figure 55.8), we can see that the number of births tends to be highest when a population is well below its carrying capacity. Therefore if we wish to maximize the number of individuals that can be harvested from a population, we should manage the population so that it is far enough below the carrying capacity to have a high birth rate. Hunting and fishing regulations are established with this objective in mind.

Populations that have high intrinsic rates of increase can persist even if harvest rates are high. In such populations (which include many fish species), each female may produce thousands or millions of eggs. In many of these fast-reproducing populations, the growth rates of individuals are density-dependent. Therefore if prereproductive individuals are harvested at a high rate, the remaining individuals may grow faster. Some fish populations can be harvested heavily on a sustained basis because a relatively small number of females can produce sufficient numbers of eggs to maintain the population.

Fish can, however, be overharvested, as illustrated by the story of the black rockfish. Many fish populations have been greatly reduced because so many individuals were harvested that the few surviving reproductive adults could not maintain the population. Georges Bank, off the northeast coast of North America—a source of cod, haddock, and other prime food

55.14 Overharvesting Can Reduce Fish Populations Populations of cod and haddock on Georges Bank—and thus harvests of these species—have crashed due to overfishing.

fishes—was exploited so heavily during the twentieth century that many fish stocks have been reduced to levels insufficient to support a commercial fishery (Figure 55.14). The haddock population has rebounded enough to support a fishery because commercial fishing of that species ceased and was restarted only after the population had recovered. In contrast, managers reduced fishing pressure on cod only slowly, and the cod population has failed to increase.

Many rapidly reproducing species can recover if overharvesting is stopped, but recovery is more difficult for slowly reproducing species. Twentieth-century whalers hunted the blue whale (*Balaenoptera musculus*), Earth's largest animal, nearly to extinction. These whales reproduce very slowly: they live up to 10 years before becoming reproductively mature, produce only one offspring at a time, and have long intervals between births. Not surprisingly, the population has failed to recover.

Whether we want to manage the sizes of populations of desirable species for sustainable harvesting or of undesirable species for control purposes, the same principles apply. If the dynamics of a pest population are influenced primarily by density-dependent regulation factors, then killing part of that population will only reduce it to a density at which it will grow faster. A more effective approach to reducing such a population is to remove its resources, thereby lowering the carrying capacity of its environment. For example, we can rid our cities of rats more easily by making garbage unavailable (reducing the carrying capacity of the rats' environment) than by poisoning rats (which only increases their reproductive rate).

Biological control is the use of natural enemies (predators, parasites, or pathogens) to reduce the population density of an economically damaging species. In many cases the target species is a pest only because it has been introduced to a new area. Natural enemies used for biological control are often obtained from the native region of the pest species. Biological control became popular in the nineteenth century after an outbreak of cottony-cushion scale, an Australian insect that attacks citrus, appeared in the citrus groves in California. A predaceous

Bufo marinus

55.15 Biological Control Gone Awry The Central American cane toad not only failed to control destructive beetles in Australia's sugarcane fields, but increased dramatically in abundance and now threatens many native Australian species (including the native frog this individual is eating).

ladybeetle and a parasitic fly were then introduced from Australia. Within a year of their release, these insects brought the scales under control.

Sometimes, however, introduced natural enemies not only fail to have any effect on the pest they were imported to control but also, freed of their own enemies, become pests themselves. This fact underlies the horror story of the cane toad (*Bufo marinus*) in Australia. This Central American toad (Figure 55.15) was introduced to control cane beetles attacking Australian sugarcane fields. But Australian cane beetles stay high on the upper stalks of the plants; the toads could not reach that high, and thus had no effect on the beetle population. Unfortunately, they had massive effects on other species.

All stages of the *B. marinus* life cycle are poisonous, and Australian reptiles (including snakes and lizards) and mammals that eat them usually die. With no enemies to limit their population growth, cane toads grow fast and outcompete native amphibian species for resources. The toads have spread from northern Australia down the east coast, where they threaten native frog species by preying on them as well as by competing with them. The Australian government is forced to spend millions of dollars in attempting to reduce their numbers.

Human population growth has been exponential

In 1798 Thomas Robert Malthus, in his *Essay on the Principle of Population*, pointed out that the human population was growing exponentially but its food supply was not, and argued that at some point, famine and death would be the ultimate fate of the human race. Malthus could not have anticipated the technological innovations over the next 200 years that would greatly enhance the capacity of humans to produce

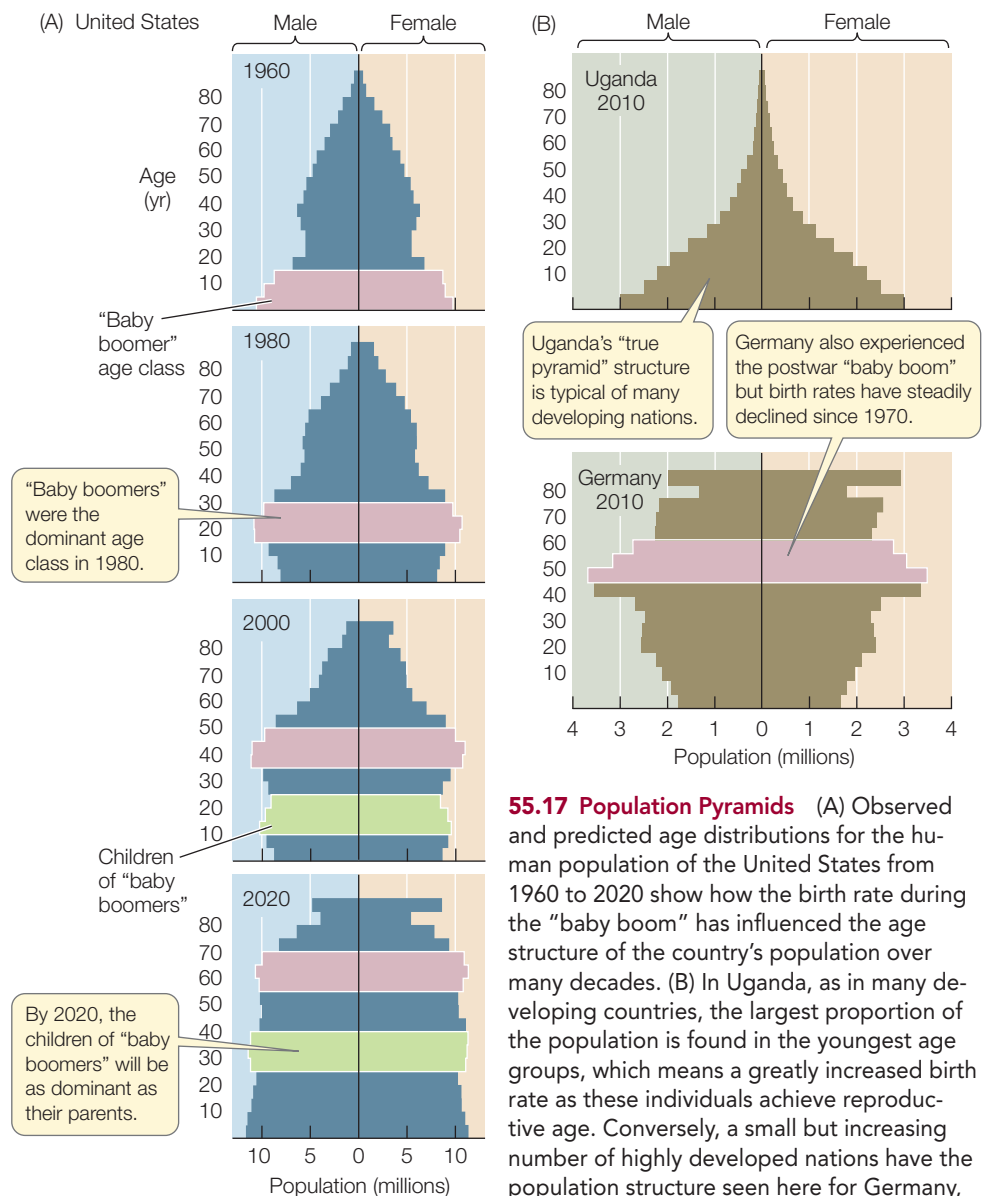

55.16 The Human Population Is Growing Exponentially The growth rate of the human population has slowed somewhat, but its large size means that millions more people are still being added every year.

food. Today, however, the size of the human population is once again a serious concern as we confront the effects of our contributions to pollution, habitat destruction, and extinctions of other species.

For thousands of years, Earth's carrying capacity for humans was low because of the relative inefficiency with which we could obtain food and water. The development of social systems and communication, the domestication of plants and animals, ever-increasing crop and livestock yields due to ongoing technological advances, and our increasing proficiency at managing diseases all contributed to unprecedented growth of the human population. It took more than 10,000 years for the population to reach 1 billion, which happened in the early nineteenth century. Today, a mere 200 years later, the planet is home to more than 7 billion human beings (Figure 55.16). Population growth has slowed somewhat from its post-World War II highs—estimates place the current worldwide rate of increase to be about 1.1 percent per year—but with a base of 7 billion, even a minimal growth rate means millions more individuals each year.

Human populations are not growing at the same pace across the world. As we saw for elephants in Figure 55.2, in long-lived species the timing of births and deaths affects a population's age distribution for many years. Between 1946 and 1964, the United States experienced a "baby boom." During those years almost 75 million babies were born, and the average number of children per family grew from 2.5 to 3.8. U.S. birth rates declined during the 1960s, but in the 1970s and 1980s the baby boomers became parents, generating another demographic bulge—a "baby boom echo" (Figure 55.17A). Today this "echo generation" is on the threshold of becoming the dominant age class.

The age structure of the U.S. population is typical of that of many industrialized nations, but a few highly developed nations (particularly in Europe) are experiencing population declines. In the developing world, however, many countries are experiencing exponential growth rates and have populations

55.17 Population Pyramids (A) Observed and predicted age distributions for the human population of the United States from 1960 to 2020 show how the birth rate during the "baby boom" has influenced the age structure of the country's population over many decades. (B) In Uganda, as in many developing countries, the largest proportion of the population is found in the youngest age groups, which means a greatly increased birth rate as these individuals achieve reproductive age. Conversely, a small but increasing number of highly developed nations have the population structure seen here for Germany, which presages a population decline.

highly skewed toward younger age classes, portending high rates of population growth in the future (Figure 55.17B). Population growth rate, of course, is only one measure of human impact on the environment; the ways in which populations use resources are critical as well, as we will discuss further in Chapters 58 and 59.

RECAP 55.6

Efforts to manage populations are more likely to be successful if they are based on an understanding of life histories and population dynamics.

- Describe an effective strategy for reducing a pest population and explain why it is effective. **See p. 1164**
- How have humans changed the carrying capacity of Earth for our own population? **See p. 1165**

Why did introduced reindeer populations persist on the island of South Georgia but not on the island of St. Matthew?

ANSWER

The different fates of the reindeer populations on these two islands reflect differences not only in the physical conditions on the islands but also in the history and purpose of the reindeer introductions. In physical terms, average climate conditions on St. Matthew are harsher than those on South Georgia; catastrophic weather events such as the winter that essentially wiped out the St. Matthew reindeer are far less frequent on South Georgia. Stability in population size is often related to stability in environmental conditions.

In terms of history, the reindeer on South Georgia were brought there by men involved in the whaling trade with the goal of establishing a food supply for ships traveling through the area. As

a consequence, the population experienced regular harvesting (initially by whalers, who shot the reindeer for food, and later by scientists who shot them for research purposes).

That the reindeer population on South Georgia has not crashed, however, does not mean it is at a desirable size. Reindeer densities range from 40 to 85 animals per square kilometer—almost 10 times higher than densities in areas where reindeer are native. At these high densities, the reindeer are having negative effects on South Georgia's native plants and animals, such as the burrow-nesting white-chinned petrel. In February 2011, plans were made to eradicate the reindeer on South Georgia in the hope of preserving the native species.

CHAPTER SUMMARY 55

55.1 How Do Ecologists Measure Populations?

- A **population** consists of the individuals of a species that interact with one another within a particular area at a particular time.
- The **density** of a population is the number of individuals per unit of area or volume.
- Ecologists have developed many ways of counting individuals as well as ways of estimating population sizes from a sample, such as the **mark-recapture method**. **Review Figure 55.2**
- Populations have a characteristic **age structure** and pattern of **dispersion**. **Review Figures 55.3, 55.4, ANIMATED TUTORIAL 55.1**

55.2 How Do Ecologists Study Population Dynamics?

- **Demographic events**—births, deaths, immigration, and emigration—determine the size of a population.
- **Life tables** provide summaries of demographic events in a population. A cohort life table tracks a **cohort** of individuals born at the same time and records the **survivorship** and **fecundity** of those individuals over time. **Review Table 55.1**
- Life table data can be used to construct a **survivorship curve**. Ecologists describe three general types of survivorship curves, which reflect different life history patterns. **Review Figure 55.5**
- The **life history strategy** of an organism describes how it partitions its time and energy among growth, maintenance, and reproduction.

55.3 How Do Environmental Conditions Affect Life Histories?

- A population's **per capita growth rate** (r) is the difference between the per capita birth rate (b) and the per capita death rate (d).
- Life history traits within a species may vary with habitat.
- Interactions with other species and the abiotic environment can influence the evolution of a species' life history traits.

55.4 What Factors Limit Population Densities?

- Populations can exhibit **exponential growth** for short periods, but eventually their resources become depleted, causing birth rates to drop and death rates to rise. **Review Figure 55.7, ANIMATED TUTORIAL 55.2**
- **Logistic growth** is the pattern seen when the growth of a population slows as its density approaches the environmental **carrying capacity** (K). **Review Figure 55.8, ANIMATED TUTORIAL 55.3, ACTIVITY 55.1**
- Species that are **r-strategists** have life histories that allow for high intrinsic rates of increase. **K-strategists** persist at or near the carrying capacity (K) of their environment. Many species' life history strategies fall along a continuum between these two extremes. **Review Figure 55.9**
- Population densities are determined by both **density-dependent** and **density-independent** factors. Several factors—including resource abundance, body size, and social organization—influence population densities.

continued

55.5 How Does Habitat Variation Affect Population Dynamics?

- No species is found everywhere within its range. Members of most species live in distinct **habitat patches**.
- A **metapopulation** consists of separate **subpopulations** among which some individuals move on a regular basis. **Review Figure 55.11**
- Extinction of a subpopulation may be prevented by immigration of individuals from another subpopulation, a process known as the **rescue effect**. **Corridors** between patches may facilitate such movement. **Review Figure 55.12, ANIMATED TUTORIAL 55.4**

55.6 How Can We Use Ecological Principles to Manage Populations?

- To manage populations, it is important to understand their life histories and population dynamics. To maximize the number of individuals that can be harvested from a population, the population should be kept well below carrying capacity.
- Reducing the carrying capacity of the environment for a pest species is a more effective way to reduce its population than killing its members.
- Earth's carrying capacity for humans depends on our use of resources and the effects of our activities on the environment. Human populations grow at different rates in different parts of the world. **Review Figures 55.16, 55.17**

CHAPTERREVIEW

REMEMBERING

1. A group of individuals of the same species born at the same time is known as a
 - a. deme.
 - b. subpopulation.
 - c. Mendelian population.
 - d. cohort.
 - e. taxon.
2. A population whose size remains constant at its carrying capacity is exhibiting
 - a. exponential growth.
 - b. geometric growth.
 - c. logistic growth.
 - d. J-shaped growth.
 - e. negative growth.
3. The process by which immigrants prevent a subpopulation from becoming extinct is called the
 - a. colonization effect.
 - b. rescue effect.
 - c. metapopulation effect.
 - d. genetic drift effect.
 - e. salvage effect.
4. Which of the following mortality factors is *least* likely to act in a density-dependent manner?
 - a. Predation
 - b. Disease
 - c. Food supply
 - d. Fire
 - e. All of these factors act in a density-dependent manner.

5. The best way to reduce the population of an undesirable species in the long term is to
 - a. reduce the carrying capacity of the environment for the species.
 - b. selectively kill reproducing adults.
 - c. selectively kill prereproductive individuals.
 - d. attempt to kill individuals of all ages.
 - e. sterilize individuals.
6. Populations that are most readily overharvested are characterized by having
 - a. very long-lived adults.
 - b. short prereproductive periods and many offspring.
 - c. short prereproductive periods and few offspring.
 - d. long prereproductive periods and few offspring.
 - e. long prereproductive periods and many offspring.

UNDERSTANDING & APPLYING

7. Most organisms that humans manage for higher densities are long-lived and have low reproductive rates, whereas most organisms that humans want to reduce in numbers are short-lived but have high reproductive rates. What is the significance of these differences for management strategies and the effectiveness of management practices?
8. In the mid-nineteenth century, the human population of Ireland was largely dependent on a single food crop, the potato. When a disease caused the potato crop to fail, the Irish population declined drastically for three reasons: (1) a large percent of the population emigrated to the United States and other countries; (2) the average age of a woman at marriage increased from about 20 to about 30 years; and (3) many people starved to death. None of these social changes were planned at the national level, yet they all contributed to adjusting the population size to the new carrying capacity. Discuss the ecological principles involved, using examples from other species.

ANALYZING & EVALUATING

9. One method of controlling introduced pest species is to introduce a natural enemy (a predator, parasite, or pathogen) from the pest's native habitat to reduce its population density. However, some species introduced to control a pest have become pests themselves. Some scientists argue that biological controls should not be used under any circumstances for pest management. Others argue that, provided they are properly studied and thoroughly vetted, we should continue to use biological control organisms as part of our set of tools for managing pests. Which view do you support, and why?
10. Section 55.5 described two studies of the effects of corridors on metapopulation dynamics—one on tiny arthropods with limited dispersal abilities (see Figure 55.12) and another on birds of tropical forests in Mexico (see p. 1162). Given the differences in size and mobility between tiny, wingless arthropods and forest birds, is it possible to come up with a general definition of a corridor? How could an investigator conduct a single experiment to determine the effects of corridors on multiple organisms that differ widely in size and mobility? Is it important to consider more than one group of organisms in trying to understand the effects of corridors in fragmented habitats?

CHAPTER OUTLINE

- 56.1** What Types of Interactions Do Ecologists Study?
- 56.2** How Do Antagonistic Interactions Evolve?
- 56.3** How Do Mutualistic Interactions Evolve?
- 56.4** What Are the Outcomes of Competition?

NOT MANY INSECTS can claim to have been the subject of a Hollywood film-making feud, but ants are an exception. In 1998 two animated films from competing studios, *Antz* and *A Bug's Life*, were released within a month of each other. Whether as animated entertainment or the subject of scientific study, the behaviors of these social insects have long fascinated humans.

The 50 or so species of leafcutter or “parasol” ants owe their name to their habit of clipping bits of leaves and holding the pieces above their heads like parasols as they cart them off to their nests. The ants don’t eat the leaf matter they collect, however. The cut leaves will serve as a substrate for growing the fungi on which leafcutter ants feed.

When a new queen ant leaves her mother’s nest, she takes with her a portion of the fungal mass on which she was raised. After mating, she digs into the soil to form a tunnel ending in a chamber, in which she places the pellet of fungus and lays eggs. Her offspring eat the fungus and develop into pint-size workers, which then collect leaf material to “feed” the fungus. As the fungus garden expands, the ants construct more nest chambers. In 3 years the number of workers in a nest can reach 8 million and the nest can measure more than 30 meters across. More than 2 kilograms of leaves each day are needed to maintain an average colony’s fungus garden, so these ants can easily strip an area of vegetation. Fungus production on a large scale necessitates a division of labor; different individuals harvest leaf pieces, care for the fungus, defend the

Fungus Farmers *Atta cephalotes* is one Central American species of leafcutter ant. Leafcutter ants harvest and transport leaf fragments to their nests where the vegetation will nourish a thriving crop of fungus, which the ants consume.

nest, clear trails for the leaf collectors, and guard the leaf fragments being carried back to the nest.

The fungi in leafcutter nests cannot exist without the ants, which supply the fungi with leaves to grow on and add fertilizer in the form of their fecal droplets. Leafcutter ants even evaluate leaves, avoiding those that contain fungus-killing chemicals. The fungal gardens, however, are vulnerable to invasion by undesirable microbes. To fend off one such invader, the green mold *Escovopsis*, the ants bring in another partner. They have special structures for carrying *Pseudonocardia* bacteria, which manufacture powerful antibiotics that suppress the unwelcome mold but do no harm to the cultivated fungus. Also present are *Klebsiella* bacteria, which fix atmospheric nitrogen to help fertilize the fungus garden and satisfy ant nutritional requirements. No doubt other organisms lurk in the fungus gardens awaiting discovery by curious ecologists or future filmmakers.

The fungi in leafcutter nests cannot survive without the ants, but can leafcutter ants survive without the fungus?

See answer on p. 1185.

56.1 What Types of Interactions Do Ecologists Study?

One of life’s certainties is that, at some point between birth and death, every individual will encounter and interact with individuals of other species. These interactions have consequences that can affect each individual’s fitness. Thus they can influence the densities of populations and the distributions of species, and, over the long term, they can lead to evolutionary change in one or more of the interacting species.

Interactions among species can be grouped into several categories

Although the kinds of interactions that take place among living things on Earth are essentially limitless, ecologists group interactions among species into a few basic categories. These categories reflect whether the outcome of the interactions is positive (+), negative (–), or neutral (0) for each of the species involved (Figure 56.1). We will introduce five broad categories of species interactions in this chapter.

ANTAGONISTIC INTERACTIONS Antagonistic interactions are those in which one species benefits and the other is harmed. Antagonistic interactions include three basic types:

- **Predation**, in which an individual of one species kills and consumes multiple individuals of other species (its **prey**).

(A)

Categories of Species Interactions			
Type of interaction		Effect on species 1	Effect on species 2
Antagonistic interactions	Predation (predator-prey)	+	–
	Herbivory (plant-herbivore)	+	–
	Parasitism (parasite/pathogen host)	+	–
	Mutualism	+	+
	Competition	–	–
	Commensalism (commensal-host)	+	0
	Amensalism	0	–

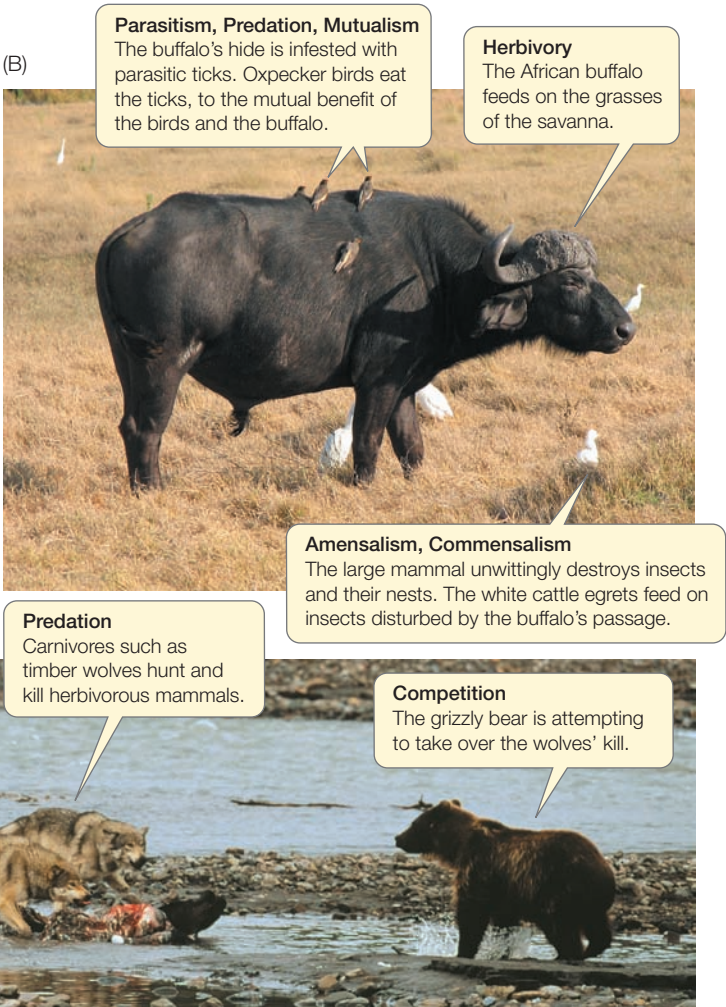

56.1 Types of Species Interactions (A) Interactions among species can be grouped into categories based on whether their influence on each of the interacting species is positive (+), negative (–), or neutral (0). (B) Even small scenes can encompass many different species interactions.

Go to Activity 56.1 Ecological Interactions
Life10e.com/ac56.1

- **Herbivory**, in which an individual of another species consumes part or (rarely) all of a plant.
- **Parasitism**, in which one species consumes only certain tissues in one or a few individuals of another species (its **host**) without necessarily killing them. Some parasites are pathogens that cause symptoms of disease in their hosts.

MUTUALISM Mutualism is a type of interaction between species that benefits both species. The interaction between leaf-cutter ants and fungi described at the opening of this chapter is an example of mutualism: the ants feed and cultivate the fungi, and the fungi, in turn, serve as food for the ants. Mutualisms exist between widely varied pairs of partners, including not only animals and fungi but also fungi and plants, animals and plants, animals and animals, and microbes and all other kinds of organisms.

COMPETITION Competition between species refers to interactions in which two or more species use the same resource. The outcomes of these interactions depend on resource availability. In some cases competitors can coexist by using the resource in different ways; if the resource is in extremely short supply,

however, the outcome can be negative for all competing species. At some point a resource may be in such short supply that a population can no longer sustain itself; when a resource becomes limiting in this way, competition becomes intense. Competition can occur along with almost any other kind of interaction: between predators that depend on the same prey species, between herbivores that feed on the same host plant, or between pathogenic microbes attacking the same host. The limiting resource need not be food; species may compete for water, for space, for nesting sites, or even (in the case of plants) for sunlight.

COMMENSALISM AND AMENSALISM Antagonistic interactions, mutualism, and competition all affect the fitness of both participants, but there are two other types of interactions that affect only one participant. **Commensalism** is a type of interaction in which one participant benefits but the other is unaffected. Most examples of commensalism (Latin, “at the same table”) involve one species feeding in, on, or around another species. For instance, one species may associate with another species that, by virtue of its own feeding behavior, makes food more accessible. Cattle egrets, for example, feed on insects disturbed by large grazing animals, but their activities have no effect on the grazers (see Figure 56.1B).

Another form of commensalism involves association for the purpose of transport, often to reach food resources that are rare and short-lived. Piles of mammal dung, for example, are a valuable resource for some detritivores, but they can be hard to find and never last long. Many kinds of detritivores that cannot fly—mites, nematodes, and even fungi—attach themselves to the bodies of dung beetles, which not only can fly but are also very good at locating fresh dung. These hitchhikers have no known effect on the dung beetles’ fitness.

Amensalism is a type of interaction in which one participant is unaffected while the other is harmed. A herd of elephants moving through a forest crushes insects and plants with each step, but the elephants are unaffected by this carnage. Amensal interactions tend to be more random, and thus less predictable, than other types of interactions.

Interaction types are not always clear-cut

Although ecologists find it useful to group interactions among species into a few basic categories, the boundaries between categories are not always clear. For example, sea anemones in the Pacific Ocean sting and eat small fish, but a select few fish species (mostly in the genus *Amphiprion*) live inside sea anemones and are unaffected by their stings. Safe from their predators, the anemonefish move freely among the stinging tentacles to scavenge the cnidarians’ leftovers (Figure 56.2).

Anemonefish must acclimate to the anemone’s venom, and the anemone, in turn, must acclimate to the fish. The acclimation process appears to involve a change in the mucus coat of the fish; wiping off the mucus of an acclimated fish results in immediate stinging, whereas anemones do not sting fish with intact mucus. The benefits of this relationship to the anemonefish are clear: it escapes its own predators by hiding behind the anemone’s stinging tentacles, and it has no need to forage

Amphiprion ocellaris

56.2 Interactions between Species Are Not Always Clear-Cut

Ecologists long believed that the relationship between sea anemones and anemonefish was a commensalism: that the fish, by living among the anemone’s stinging tentacles, gained protection from its predators. But could it also be considered a mutualism, if the fish’s feces provide the anemone with beneficial nutrients?

widely for food. But does the anemone benefit from the association? By defecating while in residence, the anemonefish may provide nitrogen-rich nutrients to the anemone. On the other hand, the fish may occasionally steal the anemone’s prey, which has a negative effect on the anemone’s fitness.

The interaction types described in this section are in reality part of a continuum, and over evolutionary time they may shift from one type to another. Their outcomes depend on both ecological and evolutionary circumstances, including the presence and influence of other species.

Some types of interactions result in coevolution

All types of interactions have the potential to influence the population densities of the interacting species. By contributing to the differential survival or reproduction of individuals with different traits, they can also alter genotype frequencies within the interacting populations over time. Thus these interactions have both ecological consequences, as when they affect the distribution and abundance of a species, and evolutionary consequences, as when they lead to adaptations. In some cases an adaptation in one species may lead to the evolution of a reciprocal adaptation in a species it interacts with, a process known as **coevolution**.

Darwin observed that evolutionary change occurs not only in response to physical conditions, as described in Chapter 54, but also in response to interactions among species. In his introduction to *On the Origin of Species*, Darwin pointed out that woodpeckers have feet, tails, beaks, and tongues “admirably adapted to catch insects under the bark of trees” as a result of their long-standing interactions with their insect prey.

While abiotic factors also act as agents of selection, they differ in a fundamental way from biotic agents of selection in that they do not themselves undergo change as a result of the interaction. Snow and ice do not become more deadly as a result of encountering cold-resistant organisms, but predators can, over evolutionary time, become swifter, more powerful, or more efficient at capturing their prey. In response, prey species may become swifter, tougher, less conspicuous, or more poisonous, all of which decrease the likelihood of being consumed.

A series of reciprocal adaptations can lead to what has been dubbed a coevolutionary **arms race**. The arms race analogy, first used in the context of interactions between herbivores and plants, can be applied to most antagonistic interactions. The evolution of traits that increase the fitness of a predator, herbivore, or parasite species exerts selection pressure on its prey or host species to counter the consumer's adaptation. The prey or host adaptation, in turn, exerts selection pressure on the consumer to improve its fitness even more, resulting in an escalating series of reciprocal adaptations.

The types of interactions most likely to lead to coevolution are those that occur predictably and with high frequency over time and that have a strong effect on the interacting species. Thus most amensal and commensal interactions are less likely to coevolve than are many antagonistic and mutualistic interactions.

Coevolution: Strategies for Survival
Life10e.com/at56.1

RECAP 56.1

Species interactions can be grouped into categories based on whether they benefit or harm each of the species involved. Some species interactions can lead to reciprocal adaptations and coevolution.

- Describe the categories of interspecific interactions. **See p. 1170 and Figure 56.1**
- What is meant by a coevolutionary arms race? **See p. 1172**

Sections 31.3 and 51.1 looked at a number of heterotrophic feeding strategies from the consumer's point of view. In the next section we will see how the antagonistic interactions—predation, herbivory, and parasitism—influence both consumer and resource species.

56.2 How Do Antagonistic Interactions Evolve?

Every species serves as a food resource, in one way or another, for at least one other species. Consumers can increase their fitness by acquiring food, whereas resource species can increase their fitness by avoiding being consumed. Thus the interests of consumer and resource species set up an antagonistic relationship that can lead to a coevolutionary arms race. These consumptive relationships need not, however, be fatal; organisms make meals of one another in many different ways.

Predator–prey interactions result in a range of adaptations

Predator–prey interactions are probably the most familiar, and the most dramatic, type of antagonistic interaction. Predators invariably kill the prey individuals they consume, and over its lifetime, a predator kills and consumes many prey individuals. Predators tend to be less specialized than other types of consumers.

The fitness of predators depends on balancing the cost of pursuing, subduing, and handling prey against the energetic benefit of consuming it, as we saw in Section 53.4. Thus many predators are larger than their prey, and many of them use strength or swiftness to capture prey. This is true of predators of all sizes: tigers pursuing deer and tiger beetles pursuing smaller insects are both fast, powerful predators and both are equipped with strong jaws (**Figure 56.3**). Predators that are smaller than their prey rely on other strategies that increase their efficiency. Many spiders, for example, capture their prey in webs. The tiny short-tailed shrew, among the smallest mammalian predators, produces venomous saliva that paralyzes not

56.3 Predators Use Many Weapons

(A) Tigers embody most people's image of a predator—a large animal that uses stealth, speed, strength, teeth, and claws to capture prey. (B) The 1.3-centimeter green tiger beetle is also formidable to its prey, including caterpillars. The beetle's huge jaws account for much of its body length, and it is one of the speediest runners among the insects.

(A) *Panthera tigris*

(B) *Cicindela campestris*

(B) *Mimetica* sp.

56.4 Avoiding Consumption by Avoiding Detection (A) The gray tree frog can change its coloration to blend in with its substrate. (B) Resemblance to an inedible object can be an effective defense against visually hunting predators. Birds searching for insect prey are likely to bypass a katydid that looks like a partially eaten leaf.

only earthworms and snails but also prey much larger than itself, including mice and small birds.

Prey species have many different kinds of defenses against predators. Many animals can escape from predators simply by flying or running away. Others have morphological defenses. Tough skin, shells, spines, or hair can foil even a determined predator. In turn, however, adaptations evolve in predators that may overcome these defenses.

AVOIDING DETECTION Prey species can often escape predators by hiding. One form of hiding is camouflage, or background matching, also called **crypsis**. Some animals can even change their coloration to match the substrate they find themselves on (Figure 56.4A). The camouflage of some species allows them to resemble objects their predators consider inedible. The katydid in Figure 56.4B, for example, looks very much like a dead leaf, even down to the likeness of a spot of fungal decay.

Because the vision of many types of predators is adapted to spot moving prey, many prey species simply stop moving if they are being pursued. “Playing possum,” a term that is sometimes applied to this strategy, refers to the ability of the opossum (*Didelphis virginiana*) to simulate death.

CHEMICAL DEFENSES Many animals use chemical defenses to escape or repel their predators. Chemical defenses are generally the province of animal prey that are small, weak, sessile, or otherwise unprotected. Among the mollusks, for example, the weaker a species’ shell, the more likely it is to use chemical defenses; for example, the sea slug in Figure 56.5B has no shell but is highly toxic. Some vertebrates also rely on chemicals to repel their predators.

Many insects produce sprays, oozes, or froths when attacked. Bombardier beetles, for example, possess a pair of glands near the anal opening. Each gland has two compartments lined with a protective cuticle. The inner compartment contains a mix of relatively nontoxic chemicals, along with hydrogen peroxide. The outer compartment contains enzymes. When the beetle is disturbed, it discharges the contents of the inner compartment into the outer compartment, which leads to an instant, energy-releasing chemical reaction. Oxygen is one of the end products generated by this reaction, and the resulting pressure discharges the mixture with an audible “pop.” Because of the energy released by the reaction, the temperature of the spray is approximately 100°C. The reaction of predators—including humans—to this hot, explosive secretion is predictable, and bombardier beetles have very few enemies.

Go to Media Clip 56.1

Bombardier Beetle Sprays Its Enemies

Life10e.com/mc56.1

But adaptations may evolve in predators that overcome their prey’s chemical defenses, as we saw in the case of the rough-skinned newt and the garter snakes that have become insensitive to its protective toxin (see Figure 21.20). Some predators are not only undeterred by their prey’s defensive chemicals, but ingest them and sequester them in their bodies as defenses against their own predators. Sea slugs are able to feed on a variety of well-defended prey with impunity and are masters at acquiring defenses from their food. Some species that feed on sponges concentrate toxic chemicals expropriated from their prey, whereas others, which feed on hydrozoans, incorporate the stinging cells of their prey, still active, into their own bodies.

APOSEMATISM Some prey species that defend themselves with toxic chemicals advertise that fact. This form of advertisement is called **aposematism**, or **warning coloration**. Aposematic prey species exploit the fact that predators can learn to avoid certain warning signals. Their warning signals may be visual (many toxic species are brightly colored) or acoustical (the rattlesnake’s warning rattle, for example), depending on what sensory cues their predators use to find prey.

Many toxic prey sport bright colors or striking patterns to protect themselves against visually orienting predators. Such warning coloration increases the probability that a predator will learn to recognize and avoid the toxic species (Figure 56.5). Some vertebrate predators that rely on visual cues can learn quickly to associate certain color patterns with an unpleasant dining experience. Thus aposematic species are characteristically tough enough to survive a brief encounter with a predator. Any encounter that results in the death of the aposematic individual is unlikely to result in selection for its aposematic pattern. Sometimes field researchers find aposematic butterflies with damage inflicted by a bird beak—an indication of having survived being tasted by an uneducated avian predator.

MIMICRY SYSTEMS Even some nontoxic species benefit from warning coloration. We have seen that some prey species avoid consumption by mimicking inedible objects (see Figure 56.4B).

(A) *Danaus plexippus* larva(B) *Chromodoris* sp.(C) *Dendrobates reticulatus*

56.5 Some Prey Come with Warning Labels Some toxic prey warn potential predators with aposematic coloration. (A) Milkweed plants are toxic, and many of the insects that feed on them, such as this monarch butterfly larva, incorporate the plant's toxic chemicals into their systems. (B) Nudibranchs (sea slugs) are mollusks without

protective shells; however, they may possess stinging nematocysts (acquired from their hydrozoan prey). (C) Poison dart frogs of Central and South America sequester highly toxic chemicals in their brightly colored skin.

Others do so by mimicking aposematic species. This strategy has led to the evolution of mimicry systems of two types. In **Batesian mimicry**, a benign, edible species (the mimic) closely resembles a dangerous, toxic species (the model) and benefits from the avoidance behavior learned by the model species' predators (**Figure 56.6A**). Mimicry may extend beyond physical appearance; many mimics also simulate distinctive behaviors of their models. In the Kalahari Desert of southern Africa, adult

Eremias lugubris lizards are cryptically colored to blend in with the sand, but juvenile lizards of this species are conspicuously black and white, resembling the dangerous oospister beetles native to the same region. Oospisters (Afrikaans for "piss in your eye"), like the bombardier beetles described earlier, can emit a noxious spray over a considerable distance. Young lizards will press their tails to the ground and arch their backs, thus enhancing their resemblance to an oospister about to "fire."

(A) Batesian mimics

*Petroscirtes breviceps*

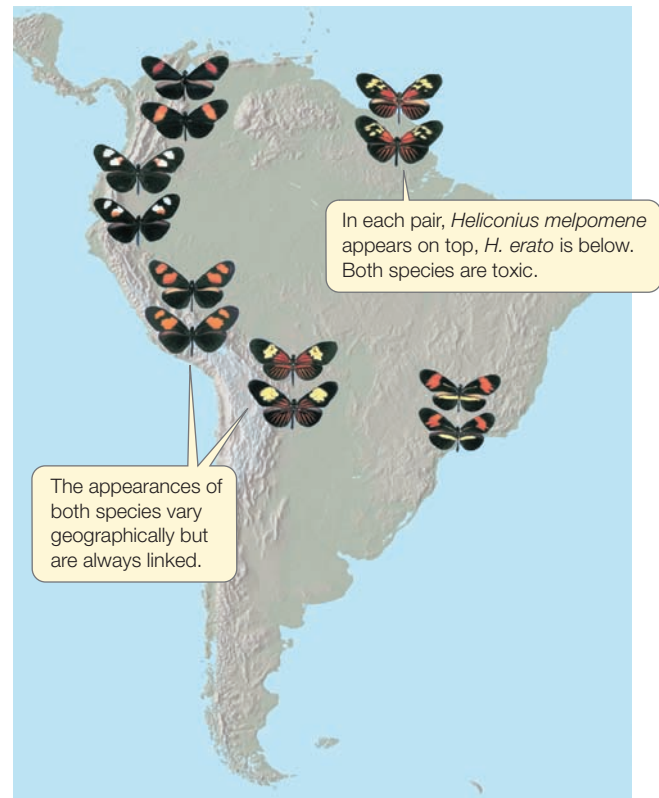

This harmless blenny...

...closely resembles a venomous related species.

*Meiacanthus grammistes*

56.6 Truth in Labeling? (A) Batesian mimics are vulnerable species that gain protection by mimicking the aposematic signals of dangerous species. The appearance of the harmless blenny species *Petroscirtes breviceps* closely resembles that of the fanged striped blenny, which possesses a pair of grooved fangs with associated venom glands. (The male fish seen here are guarding eggs that females laid inside discarded bottles on the sea-floor.) (B) The shared aposematic coloration of Müllerian mimics is an honest advertisement of their toxicity. As caterpillars, all of the longwing butterflies (genus *Heliconius*) of South America feed on toxic passionflower plants and incorporate the toxins into their adult bodies. The *Heliconius* species living together in a particular region have similar warning coloration.

(B) Müllerian mimics

In **Müllerian mimicry**, a number of aposematic species converge on a common color pattern; all benefit from providing a stronger recognition signal to predators. Many of the Neotropical longwing butterflies (*Heliconius*), which as caterpillars feed on toxic passionflower plants and incorporate the plant toxins into their bodies, are Müllerian mimics, and *Heliconius* species living together in a particular geographic region are likely to have similar coloration and share a common warning pattern (**Figure 56.6B**). Genome sequencing of *Heliconius* Müllerian mimics has identified one gene, *optix*, that codes for a transcription factor that can, by changing gene expression patterns, create the same color patterns in *Heliconius* species that are not very closely related, thus leading to the evolution of mimetic color patterns within a geographic region.

Herbivory is a widespread interaction

The most common interaction among Earth's multicellular organisms is that between plants and the herbivores that eat them. Herbivores have a relatively easy time acquiring food, since plants are sessile and cannot claw, bite, or run away. Every major class of vertebrates includes at least a few herbivores. In marine systems, organisms that feed on plants and algae include mollusks, crustaceans, echinoderms, and annelids. But in terms of numbers of individuals as well as numbers of species, the vast majority of the world's herbivores are insects.

More than 90 percent of herbivorous insects are **oligophagous**, or specialists that dine on just one or a few, often taxonomically related, plant species. **Polyphagous** species, in contrast, feed on as many as hundreds of unrelated plant species. Vertebrate herbivores are generally polyphagous; a cow grazing in a pasture, for example, can consume many different plant species in a single afternoon. There are exceptions to this pattern, however. Australian koalas famously feed exclusively on the foliage of eucalyptus trees, and the diet of giant pandas is made up almost entirely of bamboo.

Herbivores, particularly insects, generally consume only parts of their food plants and usually do not kill them. In most natural ecosystems, insects rarely remove more than 20 percent of plant biomass. For that reason, some ecologists question the ability of insects to exert selection pressure on plant traits. Mortality is not, however, the only form of selection that leads to evolutionary change; herbivores can reduce plant fitness if the plants they attack produce fewer offspring.

PLANT DEFENSES AGAINST HERBIVORES The defenses of plants against their diverse consumers are necessarily highly diverse. For most plant species, chemistry is the principal defense mechanism. As we saw at the opening of this chapter, the leaves of some plants contain chemicals that prevent them from being consumed by fungi—and thus, incidentally, from being harvested by leafcutter ants. The amazing variety of secondary metabolites produced by plants to defend themselves against herbivores is the topic of Section 39.2. Many plants, however, have additional defenses.

Some plants protect themselves by being physically difficult to ingest. Thorns and spines are effective deterrents to

browsing vertebrate herbivores. Smaller herbivores, including many insects, can be deterred by small hooked hairs on leaf surfaces. The soft bodies of leafhoppers can be pierced by these hairs, which fix the insect in place until it eventually dies from starvation or loss of blood. The plant's cuticle may also act as a physical barrier. Most grasses contain silica, which wears down sharp edges of herbivore teeth. Insects that feed only on grasses tend to have chisel-like mandibles that slice through leaf tissue, and their heads are enlarged to accommodate the larger jaw muscles needed to process their food.

RECIPROCAL ADAPTATIONS IN HERBIVORES AND PLANTS The concept of coevolution was first described in the context of interactions between herbivores and plants. In 1959 the entomologist Gottfried Fraenkel reached the conclusion after many years of study that all green plants are essentially nutritionally equivalent for insects. Why, then, are so many insects such picky eaters? Fraenkel proposed the novel hypothesis that ecological factors underlie the diversity of secondary metabolites that deter insect herbivores. A few years later, the entomologist Paul Ehrlich and the botanist Peter Raven proposed the following evolutionary scenario to account for patterns of host plant use among herbivorous insects (specifically, in their case, butterfly families):

- Certain plants, by mutation or recombination, evolve a novel secondary metabolite.
- If the chemical reduces the plant's appeal to herbivores, then plant genotypes producing the chemical are favored by natural selection.
- Freed from mortality associated with herbivory, plants possessing the novel chemical undergo an adaptive radiation.
- Certain herbivores, by mutation or recombination, evolve resistance to the chemical, and these resistant herbivores undergo their own adaptive radiation.
- With sufficient selection pressure, a resistant herbivore can evolve to use the chemical as a defense against its own predators.

This stepwise coevolutionary process explains not only the biochemical diversity of flowering plants but also the tremendous diversity of herbivorous insects. The ecological scenario outlined by Ehrlich and Raven is another example of a coevolutionary arms race.

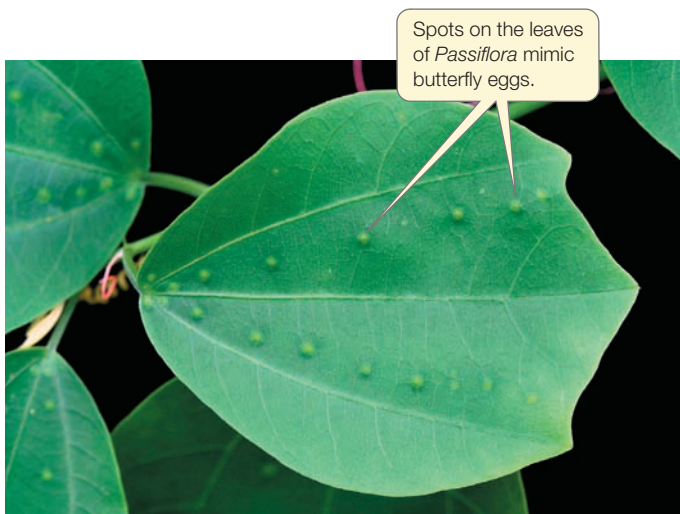

A spectacular variety of adaptations to plant defenses has evolved in herbivores. Many herbivores circumvent plant defenses by behavioral means. For example, the secondary metabolites produced by a plant called St. Johnswort (*Hypericum perforatum*) require exposure to sunlight for optimal toxicity, so some insects that feed on this plant roll its leaves into a light-impervious cylinder and feed in comfort in the dark. The laticifer-cutting beetles described in Section 39.2 have a different method of detoxifying their food plant. Many large polyphagous herbivores, such as deer, horses, and the like, graze on a wide variety of plant species, minimizing their exposure to any particular defensive chemical. Long-lived and with

relatively good memories, they can learn to avoid plants with an unpleasant taste.

Unlike large mammalian herbivores, caterpillars and many other insect herbivores may spend their entire lives feeding on a single individual plant. Such oligophagous diets are associated with highly specialized detoxification systems. The diamondback moth caterpillar eats plants in the cabbage family, which are rich in toxic mustard oil glycosides. In its gut is an enzyme that breaks down the glycosides into harmless by-products, allowing it to eat these plants with impunity.

Some herbivores take resistance a step further by storing, or sequestering, plant toxins in specialized organs or tissues that are insensitive to those toxins. In this way they can accumulate large quantities of toxins in their bodies with no ill effects. This strategy also makes the expropriated chemicals available for defense against the herbivores' own enemies. The caterpillar of the monarch butterfly, for example, is insensitive to the neurotoxic glycosides in its milkweed host plants, but most of its enemies, including insect-eating birds, cannot tolerate these compounds (as the caterpillar's aposematic coloration suggests; see Figure 56.5A).

Yet the plants continue their side of the coevolutionary arms race. As we have seen, longwing butterflies principally consume passionflower plants. These oligophagous butterflies lay eggs only on passionflower plants, and their larvae sequester host plant toxins in their bodies as they feed on the leaves. Some passionflower species, however, have modified leaf structures that resemble the eggs of butterflies. Some longwing butterfly species will not lay eggs on plants already containing eggs, so the egg mimics reduce the plant's probability of being consumed (Figure 56.7).

Spots on the leaves of *Passiflora* mimic butterfly eggs.

56.7 Using Mimicry to Avoid Herbivory The leaves of some passionflower species develop structures that resemble the eggs of their principal herbivores, longwing butterflies (*Heliconius* spp.; see Figure 56.6B). Females of many longwing butterfly species will not lay eggs on plants already containing eggs, so the egg mimics deter these females, thus protecting the plant from being eaten by hatching caterpillars.

Parasite–host interactions may be pathogenic

Parasitism is an interaction in which one species consumes only certain tissues in one or a few host individuals of another species without necessarily killing them. Keeping the host alive is important for parasites that are highly specialized; killing the host would leave the parasite with no way to make a living.

MICROPARASITES **Microparasites** are many orders of magnitude smaller than their hosts and generally live and reproduce inside their hosts. Microparasites include in their ranks viruses, bacteria, and protists. Multiple generations may reside within a single host individual, and a host may harbor thousands or millions of them. Many microparasites, in the process of acquiring nutrients at the expense of their host, cause symptoms of disease—that is, they are pathogens. Section 39.1 describes the array of secondary metabolites that plants produce to defend themselves against pathogens, and Chapter 42 describes the immune system defenses of animals.

Infection by pathogens may in some cases result in the death of the host, but death is by no means the inevitable outcome of these interactions. If a pathogen strain is to persist in a host population, the pathogens must continually infect new host individuals. A less deadly strain that kills a smaller proportion of host individuals may be able to infect a larger number of new hosts. Thus pathogen and host may reach a state of coexistence as increased host resistance (ability to withstand the effects of a pathogen) and decreased pathogen virulence (ability to cause disease) evolve. Yet new virulent strains may also arise, reminding us that the arms race goes on.

The pathogens' hosts fall into three classes: susceptible (capable of being infected), infected, or recovered (and thus, in many cases, immune). A pathogen can readily invade a host population dominated by susceptible individuals, but as the infection spreads, fewer susceptible individuals remain to be infected. Eventually a point is reached at which most infected individuals no longer transmit the infection to susceptible individuals. Thus rates of infection typically rise, then fall, and do not rise again until a sufficiently large population of susceptible host individuals has reappeared.

MACROPARASITES While microparasites generally live and reproduce inside their hosts, larger **macroparasites** are associated with their hosts in a slightly less intimate way. Although macroparasites rarely cause the same kinds of disease symptoms that pathogenic microparasites cause, they may nevertheless affect host survival and reproduction and can thereby act as selective agents on their hosts. **Ectoparasites** are macroparasites that live outside the bodies of their hosts. **Endoparasites**, such as the tapeworms described in Section 31.3, are macroparasites that spend at least part of their life cycle inside the bodies of their hosts.

Some ectoparasites—leeches, mosquitoes, and the like—are only casually associated with their hosts, interacting with them just long enough to eat their fill and then moving on. Others spend their entire lives on their hosts; these sedentary ectoparasites have a number of attributes that keep them attached

(A) *Pthirus pubis*

to their hosts. Crab lice, which are generally found in the pubic region of their human hosts, have claws on the tips of their legs that clamp around pubic hairs with great precision (Figure 56.8A). Pulling off a crab louse will often leave the legs behind, still firmly attached to the hair. Other adaptations that reduce the ability of irritated hosts to remove an ectoparasite include flattened bodies and a thick, tough cuticle. Most sedentary ectoparasitic insects are highly specialized, sometimes feeding on only a single host species.

Most hosts actively work to rid themselves of their ectoparasites. Grooming behavior—an important component of the social interactions of many primates—may have evolved in response to ectoparasites. The Japanese macaque (*Macaca fuscata*), for example, is prone to infestation by two species of lice, which tend to lay their multitudinous eggs on the outer surfaces of the host's back, arms, and legs. To keep louse populations in check, macaques form and maintain social bonds that ensure the consistent presence of grooming partners (Figure 56.8B). Some biologists believe that humans' hairlessness and bipedal posture (which freed the hands for manipulating small objects), as well as the opposable thumb, were evolutionary responses to ectoparasites.

(B) *Macaca fuscata*

56.8 Ectoparasites and Primates (A) Ectoparasites such as crab lice tend to be tiny, wingless, flattened, and equipped with strong claws for gripping. Humans are the only known host of this species, which infests the pubic hair. (B) Reciprocal grooming behaviors among primates is believed to have evolved in response to ectoparasites. Japanese macaques form social groups in which this behavior plays a significant role.

Like antagonistic interactions, mutually beneficial interactions between species can result in coevolution. A mutually beneficial exchange of goods or services can ensure the predictability and frequency of such interactions over evolutionary time; thus many mutualistic interactions are tightly coevolved.

56.3 How Do Mutualistic Interactions Evolve?

Mutualisms are interactions between two species that benefit both partners. There are few taxonomic limits on mutualistic interactions: many organisms have mutualistic partners from other domains and distant branches on the tree of life. Mutualistic interactions often arise in environments where resources are in short supply. Consequently, many mutualisms involve an exchange of food for housing or defense. Corals and their photosynthetic endosymbionts (see Figure 27.21) and lichens formed from fungi and photosynthetic algae (see Section 30.2) are examples of mutualistic interactions in which food is exchanged for housing. In another common type of mutualism, sessile organisms, particularly flowering plants, rely on more mobile species for mating or dispersal. In this chapter we will focus on mutualisms that involve animals, which can form mutualistic associations with other animals, with plants, and with a wide range of microorganisms.

Many mutualisms are asymmetrical—in other words, one party benefits more than the other. One or both partners may evolve adaptations that ensure that the exchange benefits both of them. Reciprocal adaptations are most likely to arise

RECAP 56.2

Predator–prey, herbivore–plant, and parasite–host interactions are all antagonistic. Consumers have adaptations for finding and using their resource species efficiently. Their resource species in turn have adaptations that reduce their probability of being discovered, captured, or eaten.

- What are some of the adaptations that help prey species avoid consumption by predators? [See pp. 1172–1175](#)
- How are aposematism and mimicry related? [See pp. 1173–1175 and Figures 56.4–56.6](#)
- Explain the scenario for coevolution between insect herbivores and their host plants proposed by Ehrlich and Raven. [See p. 1175](#)

in mutualistic interactions if an increase in dependence on a partner provides an increase in the benefits realized from the interaction. If increased dependence provides no selective advantage, mutualists (particularly species in asymmetrical mutualisms) may evolve into parasites, lose their partners and live independently, or even go extinct.

Some mutualistic partners exchange food for care or transport

Some organisms, such as the leafcutter ants described at the opening of this chapter, get their food by “farming” fungi. Fungus farming has been documented in a wide variety of species, including beetles, termites, and even a snail. In most cases the farmers provide housing, nutrition, and care for the fungal partner. The fungus provides food for the host, producing enzymes that degrade plant proteins and cellulose and thus converting plant materials that the insects could not have digested by themselves into an edible form.

Over the past 50 years the fungus-farming southern pine beetle (*Dendroctonus frontalis*) has destroyed huge tracts of valuable pine forests in the southeastern United States (**Figure 56.9**). The beetle owes much of its efficiency to its mutualistic partners. Masses of adult beetles attack a pine tree at once, overwhelming the tree’s ability to defend itself (the tree’s defense is to release large quantities of resin under pressure to force out the beetles). The beetles then excavate a series of galleries through the vascular tissue underneath the bark in which to lay their eggs. Female beetles also carry spores of their partner fungus into the galleries. The fungus grows on and breaks down the gallery walls, and the beetles feed directly on the fungus and the partially digested wood. The beetles also introduce a bacterium that produces an antibiotic to keep harmful bacteria from attacking the fungus (such as the leafcutter ants at the opening of this chapter). This insect–fungus–bacteria consortium overcomes the tree’s antiherbivore defenses, to the partners’ mutual benefit but to the great detriment of pine forests.

Some mutualistic partners exchange food or housing for defense

Some plants are not only food resources for insects, they are also mutualistic partners. The best known of these interactions is that between ants and acacia trees in Central America. In 1874, in Nicaragua, the naturalist Thomas Belt observed a peculiar interaction between bullhorn acacia trees (*Acacia cornigera*) and *Pseudomyrmex* ants, known as acacia ants because they are found only in association with acacias. Bullhorn acacias get their common name from the enlarged, hollow thorns, in which the ants build nests. The trees also produce rewards for the ants, both in nectar-producing extrafloral structures and modified leaflet tips that are rich in oil and protein. These structures have no apparent purpose other than providing food for ants.

Belt suggested that the notoriously aggressive acacia ants defend the plants against herbivores in exchange for food and shelter. But his idea was not tested until Daniel Janzen conducted experiments in 1966. By removing ants from some

56.9 A Mutualistic Interaction Brings Death to Pine Trees

(A) The southern pine beetle has a mutualistic relationship with a fungus, which it “farms” within the vascular tissue of pine trees. (B) The beetles excavate galleries inside the trees’ vascular tissue. Here they lay eggs and farm fungus; the fungus digests wood and provides nutrition for the larvae. (C) Masses of pine beetles have overwhelmed this forest, resulting in widespread death of pine trees.

acacias with insecticide, Janzen demonstrated that trees without ants suffered a reduction in growth and an increase in mortality (**Figure 56.10**). Although this experimental design was imperfect—the insecticides removed non-ants as well as ants from the experimental acacias and may have also influenced the ability of the trees to grow—it was the first experimental demonstration that plants may benefit from an association with ants, which is now a widely accepted concept. In fact, since Janzen conducted his experiment, additional work on ants and acacias has revealed that the ants do more than simply defend the plant against herbivorous enemies; they also clip weeds from around the base of the plants, presumably reducing competition for nutrients.

Mutualism
Life10e.com/at56.2

56.10 Are Ants and Acacias Mutualists? Bullhorn acacia trees (*Acacia cornigera*) have numerous structures that provide food and shelter for ants of the genus *Pseudomyrmex* (acacia ants). Daniel Janzen's experiments demonstrated that the trees benefit greatly

from their association with these ants, and that the energy expended in growing ant-attractive structures is repaid with increased growth and survival.^a

HYPOTHESIS *Acacia cornigera* trees deprived of their *Pseudomyrmex* ant populations will survive and grow less well than trees populated by ant colonies.

Method

1. Define a population of *A. cornigera* trees; randomly designate some of them as untreated controls and the rest as experiment subjects.
2. Fumigate the experimental trees with insecticide to eliminate all *Pseudomyrmex* ants.
3. Apply Tanglefoot® (a sticky material) to the base of the experimental trees to prevent ants from recolonizing them.
4. Record the survival and growth rates of the trees in both groups over a 10-month period.

The "bull's horns" are enlarged, hollow thorns in which the ants build nests.

Results

After 10 months, control trees (with ants) had considerably higher survival and growth rates than did trees without ant populations.

CONCLUSION *Pseudomyrmex* ants provide substantial fitness benefits to *Acacia cornigera* trees.

WORKING WITHDATA:

A Complex Species Interaction

Original Paper

Ness, J. H. 2006. A mutualism's indirect costs: The most aggressive plant bodyguards also deter pollinators. *Oikos* 113: 506–514.

Analyze the Data

As mentioned in the text, bullhorn acacias produce sugary substances on extrafloral nectaries that attract ants. Certain ant species act as pugnacious bodyguards for the plants, attacking other insects that may threaten the plants. In this way the ants and plants act as mutualists (see Figure 56.10). However, not all insects that are discouraged by ant bodyguards necessarily threaten the plant. In another such mutualism, the fishhook barrel cactus (*Ferocactus wislizeni*) of the western United States produces extrafloral nectaries that attract several species of ants. In 2003 and 2004, Joshua

Ness collected data on visitation by bee pollinators from *F. wislizeni* colonized by each of four ant species. Use the data in the table to answer the questions, explaining your reasoning in each case.

QUESTION 1

Which ant species is the best defender against herbivores?

QUESTION 2

In the presence of which ant species are bees most likely to forage?

QUESTION 3

Why do you think that the reproductive success of these plants (as measured by seed mass and number of seeds produced) varies according to which ants are guarding them?

Trait	Ant species present ^a

Plants and pollinators exchange food for pollen transport

For about three-fourths of the planet's 250,000 flowering plant species, reproduction requires the transport of pollen by an animal partner. The benefit from the plant's perspective is clear: the animal partner moves pollen from one sessile individual to another and thereby promotes sexual reproduction and thus genetic diversity. In this section we will focus on the benefits accruing to the animal pollinator.

A mutualistic pollination system requires several features:

- An attractant or reward that entices a pollinator to visit the plant
- Behavior by the pollinator that ensures it will visit more than one individual of the same plant species
- Anatomical features that allow the pollinator to transport the plant's pollen

Floral characteristics influence the type of pollinator that is attracted to a flower. Ultraviolet color patterns, for example, are highly attractive to bees (see Figure 29.15) but are invisible to most other pollinators. The depth and width of a flower can restrict the size and shape of the pollinator mouthparts that can gain access to its nectar (see Figure 23.13). The timing of a plant's flowering can also restrict the number of potential pollinator species and encourage pollinator fidelity.

Flowers entice pollinators in many ways. The most direct reward for pollinators is the pollen itself, which sometimes serves as food. Pollen was probably the original attractant in the evolutionary history of plant–pollinator interactions. Plant reproduction would not be served, however, if pollinators were to eat *all* of a plant's pollen; thus plants have evolved various adaptations to ensure that they benefit from the exchange. For example, some plants have two types of anthers: feeding anthers to produce pollen for pollinators, and fertilization anthers to produce pollen for reproduction. These two types of anthers are shaped and positioned differently, so that as the pollinator dines on pollen from the feeding anthers, the fertilization anthers deposit pollen on a part of its body that will transfer it to the stigma of another flower of the same species.

Compared with pollen, nectar—a sugar-rich solution produced by some angiosperms—is a relatively new evolutionary development. Of the floral rewards, nectar has the greatest appeal and is consumed by the widest range of animal pollinators, including birds (such as hummingbirds) and mammals (such as bats) as well as insects. While nectar is particularly effective for attracting potential pollinators, it is also prone to removal by “nectar thieves”: animals such as ants that consume the nectar without transporting pollen. Nectar thieves lower plant fitness by depleting nectar that would otherwise attract actual pollinators.

Plants may also take advantage of their pollinators. Some orchid species have evolved flowers that resemble the females of particular wasp species (sometimes even producing the same chemical substance the female wasp uses to attract mates). The plants are pollinated by male wasps that attempt to copulate with the flower (**Figure 56.11**).

Plants not only need to attract pollinators, but must also ensure that those pollinators carry their pollen to other members

56.11 Taking Advantage of a Pollinator Flowers of the orchid *Ophrys insectifera* look and smell like female *Argogorytes mystaceus* wasps. A male wasp of this species expends energy in a futile attempt to mate with the orchid's flower, getting pollen on his body in the process. The wasp then carries the pollen to the next flower he visits in his quest for a genuine mate.

of the same species. Repeat visits by a pollinator to different individuals of a particular plant species increase the likelihood that the pollen will end up on the appropriate stigma; thus some plants have adaptations to limit the diversity of their animal visitors. Botanists have long wondered why certain plants produce small amounts of toxic substances in their nectar. The nectar of tobacco flowers, for example, contains trace amounts of nicotine, an insecticidal neurotoxin. Many flower visitors, including hummingbirds, can ingest only tiny amounts of nicotine-laced nectar before moving on to other flowers. To other pollinators, however, nicotine may actually be addictive. Honey bees, for example, overwhelmingly prefer artificial nectar spiked with nicotine in laboratory tests. Putting small amounts of a potentially addictive substance in nectar may be one way tobacco plants improve their odds of a repeat visit by the right pollinator species.

Most flowers can be successfully pollinated by several different animal species. The evolution of broad suites of floral characteristics that attract certain groups of pollinators is an example of **diffuse coevolution**: the evolution of similar suites of traits in species experiencing similar selection pressures (**Table 56.1**). Scarlet gilia (*Ipomopsis aggregata*), a common wildflower in the Rocky Mountains, has successfully combined two different pollinator attraction strategies. Early in its growing season, it produces red flowers that attract hummingbirds; later in the season, the gilia shifts to producing white flowers because by then the most abundant pollinators are hawk moths, which cannot see red but are attracted to white.

A few plant–pollinator relationships are much more exclusive; these relationships lead to highly specific, rather than diffuse, coevolution. Yucca plants, for example, are pollinated only by a group of moths collectively known as yucca moths, whose

TABLE 56.1 Pollination Syndromes Resulting from Diffuse Coevolution

Preferred pollinator	Suite of anatomical traits			
	Flower shape	Flower color	Reward	Odor
Bees	Irregular	Many	Nectar, pollen	Sweet
Flesh flies	Irregular	Purplish	None	Carrion
Beetles	Bowl	White or pale	Pollen	Faint
Butterflies	Tubular	Many	Nectar	Faint
Moths	Often pendant	White or pale	Nectar	Heavy
Hummingbirds	Tubular	Red	Nectar	Imperceptible
Bats	Cuplike	White or pale	Copious nectar	Musty

larvae feed exclusively on yucca seeds. The stigma of the yucca flower is located deep within the pistil, and fertilization will not occur unless pollen is physically placed there. The specialized mouthparts of female yucca moths have distinctive long tentacles, which the moths use to pack masses of pollen from one yucca flower into transportable balls that they then carry to another flower. The moth pushes the pollen ball deep into the recess in which the flower's stigma is tucked, then turns around and deposits her eggs inside the flower's ovule (**Figure 56.12**). When the eggs hatch, the moth caterpillars will consume some—but not all—of the flower's developing seeds. Neither of these species can reproduce in the absence of the other.

Plants and frugivores exchange food for seed transport

Many animals that eat fruits (called **frugivores**) provide a valuable service to the plants that produce those fruits by dispersing seeds. Seed dispersal by animals not only offers plants the advantages of delivery to potential germination sites away from the parent plant (described in Section 38.1), but comes with the bonus of organic fertilizer for the seeds. Interactions between plants and frugivores, however, are not always reciprocal; in

many cases, one party benefits more than the other. Whereas the frugivore is paid “in advance” for its transportation services, the seeds may never reach an appropriate destination for germination (your windshield, for example, will not do). From the plant's perspective, its partnership with frugivores requires a delicate balance between discouraging them from eating fruits before the seeds are capable of germinating and attracting them when the seeds are ready. In addition, the plant must protect the seeds from destruction in the frugivore's digestive tract and defend them against inappropriate consumers that would damage the seeds or fail to disperse them at all.

The chemical process of fruit ripening ensures that fruits are most attractive to frugivores when the seeds are mature and ready for dispersal. In many fruits, ripening is accompanied by a decrease in organic acids, which make many unripe fruits sour. Color changes, which result from loss of chlorophyll and the accumulation of other pigments (the conversion of peppers from green to red during ripening is an example), have enormous signal value to many frugivores. Green, unripe fruits are generally difficult for vertebrate frugivores to see against green foliage; red and bicolored red and black fruits contrast with foliage. Fruit softens as it ripens, allowing for gentle processing by the frugivore

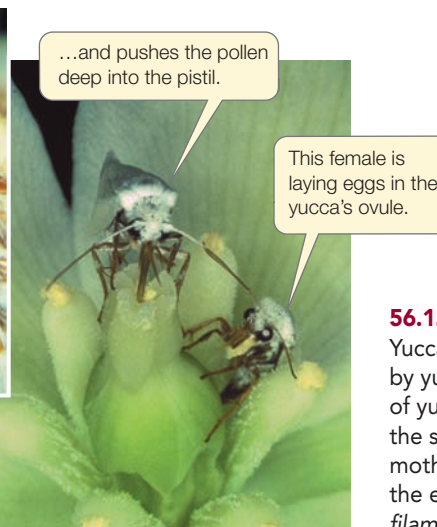

Yucca filamentosa

Tegeticula yuccasella

The female moth collects and stores pollen grains in specialized mouthparts...

...and pushes the pollen deep into the pistil.

This female is laying eggs in the yucca's ovule.

56.12 Pistil-Packing Mama

Yucca flowers are pollinated only by yucca moths, and the larvae of yucca moths feed only on the seeds of yucca plants. The moth *Tegeticula yuccasella* is the exclusive pollinator of *Yucca filamentosa*.

Dicaeum hirundinaceum**56.13 A Frugivore Plants and Fertilizes a Seed at the Same Time**

After a mistletoebird eats the fruit of the parasitic mistletoe plant, the seeds inside the fruit pass through the bird's digestive tract intact. As the seeds are voided, their sticky outer coat makes them stick to the bird's feathers. As the bird wipes itself clean on a branch, the seed sticks to the branch, where it germinates.

and rapid passage through its gut. Another conspicuous change in ripening fruits is an increase in sugar content—the “reward” most sought by frugivores. Seed coats, fruit pulp, and epidermis may all contain secondary chemicals designed to discourage inappropriate frugivores from consuming the fruit.

Because of the often asymmetrical nature of the mutualism between frugivores and plants, relatively few highly specialized frugivores exist. One apparently reciprocal interaction is between mistletoes—parasitic plants that grow on trees—and the mistletoebird that serves as the plants' primary dispersal agent in Asia and Australia (**Figure 56.13**). This bird dines largely on the fleshy berries of mistletoe. The seeds, covered with a glue-like outer coat, experience little enzymatic or mechanical damage as they pass through the thin-walled guts of the birds that swallow them. When the seeds are voided with a bird's droppings, the sticky outer coat causes the seeds to adhere to the bird's feathers, prompting it to wipe its bottom across the tree branch on which it is perched. Once the seed is wiped on the branch, the gluey coat keeps it there—in an ideal location for a mistletoe seed to germinate.

RECAP 56.3

Mutualistic interactions involve an exchange of benefits. Most plants rely on mutualisms with animals for fertilization and seed dispersal.

- Give examples of benefits that are exchanged in at least two mutualisms between plants and animals.
- What three features are required by a plant–pollinator mutualism? **See p. 1180**
- How are plant–pollinator interactions different from plant–frugivore interactions? **See pp. 1180–1181**
- Describe some adaptations in plants that help maintain the balance in their relationships with frugivores. **See p. 1181–1182**

From our discussion of interactions between two species that benefit both, we will now move to a type of interaction that benefits neither: competition. This type of interaction is widespread because it can arise wherever two or more species require the same resources.

56.4 What Are the Outcomes of Competition?

Antagonistic interactions can be quite attention-getting; the scene of a lion stalking a gazelle is almost emblematic of the African savanna. But at the same time a predator is interacting with its prey, it may also be interacting with other predators that hunt the same prey species. Lions are not the only predators of gazelles; cheetahs, hyenas, and even crocodiles hunt and kill gazelles, potentially reducing the supply of food available for lions.

Whenever any resource is not sufficiently abundant to meet the needs of all the organisms with an interest in that resource, organisms must compete with one another to gain enough of that resource to survive. Competition not only influences the evolution of species but also plays an important role in determining the structure and composition of communities, as we will see in the next chapter.

Competition is widespread because all species share resources

Virtually no species enjoys exclusive access to any given resource. The vast majority of species must compete for at least some resources with other species. As we saw in Section 55.4, limited resources are the main reason why populations do not grow indefinitely. When resources are limited, individuals in the population compete for those resources. Such **intraspecific competition**—competition among individuals of the same species—may result in reduced growth and reproductive rates for some individuals, may exclude some individuals from better habitats, and may cause the deaths of others. **Interspecific competition**—competition among individuals of different species—affects individuals in much the same way. At some point an essential resource may be in such short supply that a population is in danger of becoming unable to sustain itself; when a resource becomes limiting in this way, competition becomes intense and can influence the persistence and evolution of species.

The principle of competitive exclusion holds that no two species can share the same limiting resource indefinitely. If one species can prevent all members of another species from using the resource, the inferior competitor may go locally extinct, a result called **competitive exclusion**. In other cases, selection pressures resulting from interspecific competition cause changes in the ways in which the competing species use the limiting resource. If those changes allow the species to coexist, the result is called **resource partitioning**.

Whether it is interspecific or intraspecific, competition occurs by two major mechanisms. **Interference competition** occurs when a competitor interferes with another competitor's access to a limiting resource. **Exploitation competition** occurs when a limiting resource is available to all competitors and the

Geospiza fuliginosaNectar Use and Wingspan of *G. fuliginosa*

56.14 Competition with Bees Influences Finch Morphology On islands in the Galápagos archipelago where *Geospiza fuliginosa* is the sole pollinators of cactus flowers, a short wingspan increases these

birds' ability to negotiate the flowers. On islands where carpenter bees compete with the birds for cactus nectar, *G. fuliginosa* individuals have a longer wingspan and feed more heavily on other foods.

outcome of competition depends on the relative efficiency with which the competitors use the resource.

Interference competition may restrict habitat use

Interference competition can take many forms. A graphic example involves the desert ant *Conomyrma bicolor* and the honeypot ant *Myrmecocystus mexicanus*. These two ant species occupy the same type of habitat—arid areas containing little vegetation—and they feed on similar foods—the sugary excretions of aphids and other sap-feeding insects as well as occasional arthropods, none of which is in great supply. When *C. bicolor* workers find the entrance of a honeypot ant nest, they pick up small stones in their mandibles, carry them to the rim of the nest opening, and drop them down the hole—up to 200 stones in a 5-minute interval. This activity is enough to stop the honeypot ants from going out foraging. Some honeypot ant colonies, under constant stone-dropping attack for several weeks, may be almost entirely deprived of food.

Even microorganisms interfere with one another's use of resources. In the highly structured environment of the rhizosphere, or “root-world,” of the soil, competitive interactions can be locally intense. Many soil bacteria produce substances that subdue their microbial competitors. Actinobacteria, for example, produce chemicals that interfere with essentially every life process in other kinds of bacteria. Many of the chemicals that these remarkably well defended microbes produce to defeat their competitors are used as antibiotics by mutualistic partners, such as the bark beetles described in Section 56.3, as well as in human pharmacology.

Exploitation competition may lead to coexistence

Exploitation competition may lead to coexistence, provided that the species relying on the same resource evolve adaptations to divide up, or partition, that resource. For example, in many Rocky Mountain communities, at least three species of bees consume the nectar of *Agave schottii*, the shindagger agave. The three bee species differ in where and when they collect shindagger nectar. Honey bees tend to forage in places with the greatest numbers

of shindagger flowers, bumblebees in places with intermediate numbers of flowers, and carpenter bees where flowers are few and far between. Honey bees also tend to be most active when nectar output is greatest. With their larger nests and greater numbers of offspring to support, honey bees require greater foraging efficiency and greater energy intake. Foraging sites that are not worth their while are left to the other bees.

In some cases individuals within a species display different behaviors or morphologies depending on whether they are competing for resources with another species. Darwin remarked in *On the Origin of Species* that “Natural Selection leads to divergence of character; for more living beings can be supported on the same area the more they diverge in structure, habits, and constitutions.” This “divergence of character” is referred to today as **character displacement**. On some of the islands of the Galápagos archipelago, for example, certain cactus species are pollinated exclusively by the small ground finch *Geospiza fuliginosa*, for which cactus nectar is an important food source (see Figure 23.8). On other islands, a carpenter bee (*Xylocopa darwinii*) competes with the finches for cactus nectar; the birds consequently feed more heavily on seeds and insects. On the islands where bees are absent, the birds feed on nectar more often and have smaller wingspans than on islands where they share cacti with bees (Figure 56.14).

Sometimes organisms respond to competition by changing their location to avoid confrontations. The African wild dog (*Lycaon pictus*) is a carnivore that lives and forages in packs (groups of related individuals). Frequent vocalizations, called twitters, function to keep the pack together, but these acoustical signals also can alert their chief competitors for prey, African lions (*Panthera leo*). Lions hearing the dogs' twitters can use them to locate dog packs and steal their kills. The dogs avoid competing with lions by selecting areas for their dens where the likelihood of being overheard by lions is low; thus wild dog densities are inversely correlated with lion densities. The wild dog is considered a **fugitive species**—a species that leaves an otherwise suitable habitat in order to avoid competition with another species.

Species may compete indirectly for a resource

Species may compete indirectly for a resource even when they are not present in the same habitat at the same time. Sometimes a species so alters the quality of a resource that it is rendered less usable by other species that may encounter it afterward. For example, feeding by sap-sucking leafhoppers on potato plants early in the growing season can cause curled leaves and chlorosis (loss of chlorophyll). Potato beetles feed on potato plants later in the growing season. Beetles that consume leaves damaged by leafhoppers suffer reduced growth and survival rates. Even though these two herbivores do not feed at the same time, one species influences the use of the shared food resource by its competitor.

Indirect competition can also result when two species share a common predator. For example, the parasitoid wasp *Venturia canescens* is a consumer of two different species of caterpillars that infest stored food products such as flour, the Indianmeal moth caterpillar (*Plodia interpunctella*) and the Mediterranean flour moth caterpillar (*Ephestia kuehniella*). The two caterpillar species can coexist in a flour bin, but when the wasp is present, it preferentially attacks and kills the flour moth caterpillars. Thus in the presence of the wasp, the competitive balance between the two caterpillar species is altered in the meal moth's favor. This type of competition is indirect because the outcome of competition depends not on how the two competitors use the shared resource, but on how the two competitors interact with a shared predator.

Competition may determine a species' niche

Competition is important in determining where a species can be found. A species' **niche** is the set of physical and biological conditions it requires to survive, grow, and reproduce. Thus a species' niche is partly defined by the resources available in the environment. Although a species might be physiologically able to live under a wide range of conditions, competitors may restrict its use of resources in a particular location. Thus every species has a **fundamental niche**, defined by its physiological capabilities, and a **realized niche**, defined by its interactions with other species.

Two species of barnacles, the rock barnacle (*Semibalanus balanoides*) and Poll's stellate barnacle (*Chthamalus stellatus*), compete for space on the rocky shorelines of the North Atlantic Ocean. The planktonic larvae of both species settle in the intertidal zone and metamorphose into sessile adults. The smaller stellate barnacles generally live at higher levels in the intertidal zone, where they face longer periods of exposure and desiccation (drying out) than do rock barnacles, which live at a lower level. There is little overlap between the areas occupied by adults of the two species (Figure 56.15). What explains their distinct distributions in the intertidal zone?

In a famous study conducted more than 50 years ago, Joseph Connell experimentally removed one or the other species from

56.15 Interspecific Competition Can Restrict a Species' Range Interspecific competition with rock barnacles (*Semibalanus*) restricts stellate barnacles (*Chthamalus*) to a smaller portion of the intertidal zone than they could otherwise occupy. Larvae of both species settle throughout the intertidal, but at lower levels, rock barnacles grow much faster and eliminate the stellate barnacle larvae. In the upper reaches of the intertidal, however, the greater susceptibility of rock barnacles to desiccation (drying out) allows stellate barnacles to outcompete them. The two species can coexist in a small portion of the intertidal zone.

its characteristic zone and observed the response of the remaining species. Stellate barnacle larvae normally settle in large numbers throughout much of the intertidal zone, including the lower levels where rock barnacles are found (their fundamental niche), but they thrive at those lower levels only when rock barnacles are not present (their realized niche). Connell found that the rock barnacles grew so fast they smothered, crushed, or undercut the stellate barnacle larvae. However, removing stellate barnacles from their spots higher in the intertidal zone did not lead to their replacement by rock barnacles; the rock barnacles are less tolerant of desiccation and failed to thrive there even when stellate barnacles were absent. The result of the competitive interaction between the two species is a distinctive pattern of intertidal zonation, with stellate barnacles restricted in their distribution by competition and rock barnacles restricted in their distribution by their physiological limitations.

RECAP 56.4

Competition occurs when two or more species require a resource that is in limited supply. No two species can share the same limiting resource indefinitely. The outcome of competition may be competitive exclusion, in the form of local extinction, or coexistence, in the form of resource partitioning.

- How does exploitation competition differ from interference competition? **See pp. 1182–1183**
- How can competition lead to character displacement? **See p. 1183 and Figure 56.14**
- Explain the difference between an organism's fundamental niche and its realized niche. **See p. 1184 and Figure 56.15**

56.16 A Fungal Garden Cutaway view of a South American leaf-cutter ant nest chamber filled with fungus. Several winged ants (*Atta colombica*) can be seen in the crevices of the fungal mass.

The study of interactions among the species in a community is a large part of community ecology—the topic of the next chapter. Every kind of interaction we have studied in this chapter influences the nature and structure of communities. Competition helps determine which species persist and which go extinct, as well as dictating how many different species can be supported by a particular resource. Similarly, antagonistic interactions have important effects on the distribution and abundance of consumer and resource species, and the presence of mutualistic partners may dictate whether a particular species can exist in a particular community.

The fungi in leafcutter nests cannot survive without the ants, but can leafcutter ants survive without the fungus?

ANSWER

The relationship between the leafcutter ants and their fungi is a coevolved mutualism. The ants are so specialized behaviorally that they would starve without their fungus gardens. Recent sequencing of the genome of one leafcutter species, *Atta cephalotes*, revealed that this species has lost several genes possessed by other ants. Those genes include the ones encoding the entire pathway for biosynthesizing the amino acid argi-

nine, which the leafcutter obtains from its fungal food, as well as several genes that break down plant toxins (which the fungus does for the leafcutter as it metabolizes the leaf substrate). In the case of leafcutter ants and fungi, we can assume that the increasing dependence of each species on its partner provided it with an increase in benefits from the partnership, resulting in reciprocal adaptations.

CHAPTER SUMMARY 56

56.1 What Types of Interactions Do Ecologists Study?

- Species interactions can be grouped into categories. **Antagonistic interactions** include **predation**, **herbivory**, and **parasitism**, all of which benefit a consumer while harming the species that is consumed. **Mutualism** benefits both participants, whereas **competition** harms both. **Commensalism** benefits one participant with no effect on the other; **amensalism** has no effect on one participant but harms the other. **Review Figure 56.1, ACTIVITY 56.1**
- The evolution of an adaptation in one species may lead to the evolution of an adaptation in a species with which it interacts, a process known as **coevolution**. A series of reciprocal adaptations among consumers and their resource species can lead to a coevolutionary **arms race**. **See ANIMATED TUTORIAL 56.1**

56.2 How Do Antagonistic Interactions Evolve?

- Predators kill the individuals they consume (their prey). Over its lifetime, a predator kills and consumes many prey individuals.
- Some prey species avoid detection by means such as **crypsis**. Others defend themselves by physical or chemical means. Chemically defended animals often advertise their toxicity with **aposematism**, or warning coloration. **Review Figure 56.4, 56.5**
- In **Batesian mimicry**, a nontoxic species mimics a toxic species. In **Müllerian mimicry**, two or more toxic species converge to resemble one another. **Review Figure 56.6**

- Herbivores generally consume only parts of their food plants and usually do not kill them.
- Many herbivores have evolved resistance to the defensive secondary metabolites produced by plants, and some have incorporated them into their own defenses against predators.
- Parasites consume certain tissues in one or a few host individuals of another species without necessarily killing them. **Microparasites** include viruses, bacteria, and protists; large numbers of these organisms can live and reproduce within the body of the host and are often pathogenic. **Macroparasites** are less intimately associated with their hosts but can nonetheless affect host fitness.

56.3 How Do Mutualistic Interactions Evolve?

- Mutualistic interactions involve an exchange of benefits. Many mutualisms arise in environments where resources are in short supply.
- Reciprocal adaptations are most likely to arise when an increase in dependency on a partner provides an increase in the benefits realized from the interaction.
- Some animals “farm” fungal species, which provide them with food. Other mutualisms involve an exchange of food or housing for defense. **Review Figures 56.9, 56.10, ANIMATED TUTORIAL 56.2**

continued

- Many mutualisms between plants and animals involve an exchange of food for transport. In plant–pollinator interactions, animals that collect and transport pollen are rewarded with pollen or nectar.
- Broad suites of floral characteristics that are attractive to certain types of pollinators exemplify **diffuse coevolution**. Some plant–pollinator mutualisms, however, are much more specific and exclusive. **Review Figure 56.11, Table 56.1**
- Plants that depend on **frugivores** for seed dispersal must balance the need to discourage frugivores from eating fruits before the seeds are mature, attract frugivores when the seeds are mature, and protect the seeds from destruction in a frugivore’s digestive tract.

56.4 What Are the Outcomes of Competition?

- Competition occurs whenever a resource is not sufficient to meet the needs of all organisms with an interest in that resource.
- Competition may result in local extinction of the inferior competitor, an outcome called **competitive exclusion**. Alternatively, selection pressures resulting from competition may change the ways in which the competing species use a limiting resource, an outcome called **resource partitioning**. **Interference**

competition occurs when an individual interferes with a competitor’s access to a limiting resource. **Exploitation competition** occurs when a limiting resource is available to all competitors and the outcome of competition depends on the relative efficiency with which competitors use the resource.

- Exploitation competition may lead to **character displacement**, in which attributes of a species vary depending on whether a competitor is present or absent. **Review Figure 56.14**
- Species may compete indirectly even when they are not present in the same place at the same time, as, for example, when they share a common predator.
- A species’ **niche** is the set of physical and biological conditions it requires to persist. Although a species may be able to persist under a wide range of resource conditions (its **fundamental niche**), competitors may restrict its use of resources in a particular location (its **realized niche**). **Review Figure 56.15**

CHAPTERREVIEW

REMEMBERING

- Predation, herbivory, and parasitism are all examples of
 - antagonistic interactions.
 - mutualistic interactions.
 - commensal interactions.
 - amensal interactions.
 - competitive interactions.
- In a coevolutionary arms race, after a plant evolves a novel chemical defense against an herbivore,
 - the herbivore can be expected to go extinct.
 - the plant can be expected to undergo a range restriction because of the cost of producing the novel chemical.
 - the herbivore can be expected to evolve resistance to the plant’s defense.
 - the plant can be expected to experience reduced fitness because of the cost of producing the novel chemical.
 - the plant can be expected to stop producing other types of defenses.
- Damage caused to shrubs by branches falling from overhead trees is an example of
 - interference competition.
 - predation.
 - amensalism.
 - commensalism.
 - diffuse coevolution.

- A hummingbird sips nectar from the flowers of a plant, pollinating those flowers in the process. This interaction is best classified as
 - parasitism, because the hummingbird consumes the flower’s nectar.
 - predation, because the hummingbird eats the plant’s seeds.
 - commensalism, because the hummingbird benefits from consuming nectar and the plant is unaffected.
 - mutualism, because the plant provides nectar for the hummingbird and the hummingbird transports pollen for the plant.
 - Not enough information is provided to classify this interaction.
- One factor that can constrain the realized niche occupied by an organism is
 - crypsis
 - aposematism.
 - mimicry.
 - commensalism.
 - competition.

UNDERSTANDING & APPLYING

- The different types of interspecific interactions are part of a continuum, and their outcomes often depend on circumstances. Refer to the Working with Data exercise on p. 1179. How does this example exemplify the various types of interspecific interactions (mutualism, competition, predation, parasitism, commensalism)? Do you think a continuum is represented here? What aspects of the situation described by the data could change the interactions?

7. Like the southern pine beetle in Figure 56.9, the mountain pine beetle (*Dendroctonus ponderosae*) attacks pine trees with the help of a symbiotic fungus that infects the host tree. In 2009 these beetles infested almost 4 million acres of pine forest across Montana, Wyoming, Colorado, Idaho, Utah, Oregon, and Washington. How would you determine which pine trees are susceptible to mountain pine beetle attack? How could the fact that this beetle has a symbiotic partner affect approaches for managing the outbreak?
8. *Salmonella serovar typhimurium* is a bacterium that lives in the intestines of a wide variety of animals—including humans, in which it can cause gastroenteritis. In the United States, raw chicken and other poultry are frequent dietary sources of this bacterium and thus present a significant health hazard. Although warning labels now appear on packaged raw poultry, the food industry is testing new ways to reduce the likelihood of contamination by reducing *Salmonella* populations in chickens before they are slaughtered. In one such test, broiler chicks were given a culture of three species of bacteria: *Lactobacillus plantarum*, *L. acidophilus*, and *Lactococcus lactis*. These birds, along with control birds that had not ingested the cultures, were exposed to *Salmonella* gut colonization and then tested to see if they maintained populations of *Salmonella* in their guts. Chicks that had been given bacterial cultures consistently had significantly lower populations of *Salmonella* than the control group.
 - a. What ecological principle is being applied by the poultry industry?
 - b. What other ecological outcomes might this experiment have produced?
 - c. What other problems might this ecological principle be useful in tackling?

ANALYZING & EVALUATING

9. Many ectoparasites feed on only a narrow range of host species. Until recently, investigators used close genetic relationships among bird lice as evidence of close genetic relationships among their host bird species. Some ornithologists thought that flamingoes were closely related to ducks and geese, citing as evidence the observation that three of the four genera of bird lice found on flamingoes also parasitize ducks and geese. DNA analysis, however, showed that flamingoes are not close relatives of ducks, but are more closely related to grebes, another group of waterfowl. If this analysis is accurate, what would you predict about the lice parasitizing grebes? How could you use modern methods of molecular analysis to determine relationships among bird lice and their hosts? Given that grebes, ducks, and flamingoes are all water birds, what other factors might contribute to host shifts in ectoparasitic lice?
10. Even though nectar serves no function in the life of a plant other than to attract and reward pollinators, some plants produce toxic compounds in their nectar. As we've seen, in some cases these substances are addictive and encourage pollinators to revisit the same plant species; honey bees, for example, may visit tobacco flowers repeatedly because they become "addicted" to nicotine (see Section 56.3). But another study had a different outcome. Some researchers created genetically modified tobacco plants that produced different levels of nicotine in their nectar and found that higher concentrations led to shorter visits by pollinating hummingbirds and hawk moths—and more successful pollination than in plants whose flowers hosted longer visits. Why might shorter visits increase pollination success? What other factors might influence how much nicotine a tobacco plant should produce in its nectar?

CHAPTER OUTLINE

- 57.1** What Are Ecological Communities?
- 57.2** How Do Interactions among Species Influence Communities?
- 57.3** What Patterns of Species Diversity Have Ecologists Observed?
- 57.4** How Do Disturbances Affect Ecological Communities?
- 57.5** How Does Species Richness Influence Community Stability?

ONE DAY IN MARCH OF 1996, the body of an apparent suicide victim was discovered under the bushes near the railroad tracks in Cologne, Germany. The badly decomposed corpse contained masses of maggots—fly larvae—and the dried outer skin was peppered with pale yellow insect eggs. Examining the body, Mark Benecke, a forensic entomologist, recovered a single adult fly, which he identified as *Piophilidae casei*, the cheese skipper.

A diverse community of insect species colonizes human corpses, and its composition varies predictably as decomposition progresses. There are three major stages of decomposition: autolysis (degradation of proteins and lipids), putrefaction, and finally, decomposition. Each stage is characterized by a distinctive faunal community of species that use decomposing corpses in many ways. Some species, such as cheese skippers, consume dead flesh; others, such as hide beetles, eat hair and nails; still others prey on the flesh-eating insects or consume their excrement. Among these species, the cheese skippers are latecomers, arriving at corpses only when autolysis is well advanced and the body's proteins start breaking down—typically after 1 to 3 months. The abundance of cheese skipper eggs suggested to Benecke that these insects had undergone at least two generations in the corpse. Knowing that completion of the insect's life cycle required from 11 to 19 days under local weather conditions, he calculated that the first adults probably laid eggs about 90 days after death, and that 22 to 38 more days were needed to complete two generations. Thus he calculated that death must have occurred

Dead Reckoning Forensic entomologists use pig carcasses like this one as models to measure successional changes in corpse communities. They are able to apply these measurements to human corpses because pigs are in the same weight range as humans and, like humans, pigs are mostly hairless.

between 112 and 128 days earlier. As it happened, a 38-year-old woman had been reported missing about 4 months before the body was found; the estimated postmortem interval helped investigators identify her as the suicide victim found by the tracks.

What species occur where and when is the concern of community ecologists. The species present in a community can change in predictable ways, at spatial scales ranging from a dead body in a patch of shrubbery to an Amazonian rainforest, and at time scales ranging from days to millennia. But the ecological processes affecting communities are similar whatever the scale. The study of the seemingly esoteric changes in the composition of carrion communities has not only allowed ecologists to help find evidence that can identify a missing person or convict a murderer, but has also added to our understanding of ecological communities.

How do the insect species in a corpse community influence one another's ability to survive?

See answer on p. 1203.

(A) *Sarracenia purpurea*

(B)

57.1 Ecological Communities Exist at Different Scales

(A) The micro-organisms and tiny invertebrates (such as insect larvae) existing within a single pitcher plant constitute an ecological community. (B) Lake Superior in central North America is Earth's largest freshwater lake. It encompasses a large biological community with boundaries defined by its shoreline. Despite having such a defined boundary, the lake community is subject to effects from species and activities far beyond its contained waters.

57.1 What Are Ecological Communities?

In ecological terms, a **community** is a group of species that co-exist and interact within a defined area. Although each species has unique interactions with the other species in its community (as we saw in the previous chapter), ecologists often find it useful to study the properties of the community as a whole.

Communities vary greatly in size and scope. The organisms colonizing a dead body constitute one type of definable community. Another type of easily identifiable community is that living within the purple pitcher plant (*Sarracenia purpurea*), a plant common in North American wetlands (Figure 57.1A). Each plant has several leaves that form rainwater-collecting “pitchers,” and the plant derives nitrogen from insect prey that get trapped in the pitchers and drown (see Section 36.5). However, the pitchers are also occupied by thriving communities of living microorganisms and tiny invertebrates, including bacteria, protists, rotifers, and mosquito larvae.

The boundaries defining a community, particularly a large one, are not always so easy to recognize. The community of organisms inhabiting Lake Superior, for example, is for the most part bounded by the shores of the lake (Figure 57.1B). However, even though Lake Superior may appear to be self-contained, many of its components originate far away. For example, mallards and other ducks may consume seeds in one location, and in the 5 to 11 hours it takes for the seeds to move from one end of the duck digestive tract to the other, the birds may fly up to 1,400 kilometers before depositing the seeds in their excrement.

When borders become unclear, ecologists may designate boundaries somewhat arbitrarily, based on their ability to study the community. By the same token, because a community can contain thousands of different species from microscopic bacteria to towering trees, it is usually impractical or impossible to study all species within a community. Ecologists often define a community of interest taxonomically—for example, the fish community of Lake Superior.

Communities are characterized (1) by their species composition—the number and kinds of species they contain; and (2) by the relative abundances of those species. Species composition is determined by the same factors that determine the distributions of species because, as we saw in Chapter 54, a species can occur in a particular place only if it can colonize that place and if environmental conditions allow it to persist there. Thus even the same type of community may contain different numbers of species in different places. The insect community of human corpses, for example, varies with local climate and burial conditions (e.g., whether the body is buried, deposited on the soil surface, or submerged in a river or pond).

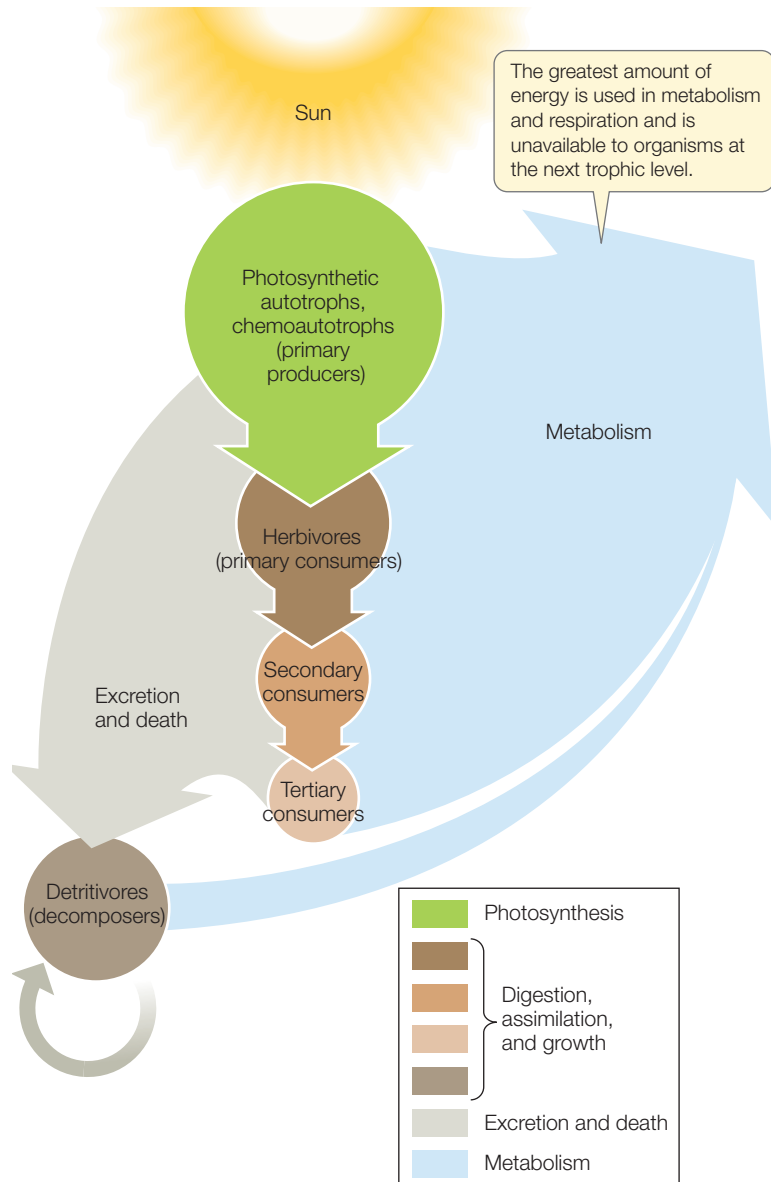

Although communities vary in size and complexity, ecologists have devised methods for quantifying basic properties of community structure and organization irrespective of their scale. These methods have revealed patterns that reflect underlying community assembly rules and general principles.

What determines how many species constitute a community in any particular place? One important factor is the amount of energy available to sustain organisms.

Energy enters communities through primary producers

Sunlight is the ultimate source of energy for most of Earth's communities. Sunlight makes photosynthesis possible, and photosynthesis, in the vast majority of communities, makes energy available to other organisms in an edible form. All nonphotosynthetic organisms (heterotrophs) consume, either directly or indirectly, the energy-rich organic molecules produced by the plants and other photosynthetic organisms that get their energy directly from sunlight (autotrophs). Photosynthetic autotrophs, along with a handful of chemoautotrophs (organisms that obtain chemical energy from inorganic molecules in their environment), are known as **primary producers**.

Gross primary productivity (GPP) is the rate at which all the primary producers in a particular community turn solar energy into stored chemical energy via photosynthesis. The energy that is accumulated by primary producers is called gross

57.2 Energy Flow through Trophic Levels Much of the energy accumulated at each trophic level is lost (often as heat) to metabolism and respiration by the organisms at that level. In this diagram, the width of each arrow is roughly proportional to the amount of energy flowing through that channel. Arrows indicate directions of energy flow.

Go to Activity 57.1

Energy Flow through an Ecological Community

Life10e.com/ac57.1

primary production. (The terms “productivity” and “production” are often used interchangeably: “productivity” is the rate of energy accumulation; “production” is a measure of accumulated energy as a product.)

Not all GPP accumulated by primary producers becomes available to heterotrophs because primary producers use some of that energy for their own respiration and other metabolic processes. **Net primary productivity (NPP)** is the rate at which energy is incorporated into primary producers’ bodies through growth and reproduction. Thus net primary

production can be measured as the amount of primary producer biomass (the weight of organic matter) that is available for consumption by heterotrophs. This relationship is described mathematically as

$$\text{NPP} = \text{GPP} - \text{R}$$

where R is the energy lost through respiration. These relationships are represented in a highly simplified form in **Figure 57.2**.

Consumers use diverse sources of energy

A **food chain** is a diagram that depicts the linear sequence of who eats whom in a given community. Food chains can be interwoven into a more realistic depiction of community feeding relationships, called a **food web** (**Figure 57.3**). Most communities contain so many species interacting in so many different ways that it is impossible to enumerate (or even identify) all of the links. Nevertheless, simplified food webs are useful in envisioning the sequence of energy flow through a community. An organism’s **trophic level** indicates where in that sequence it obtains its energy (**Table 57.1**). Primary producers start the chain of trophic levels. At the next level are **primary consumers**—the herbivores that dine on the primary producers. Organisms that eat herbivores, called **secondary consumers**, are the next trophic level. Those that eat secondary consumers are tertiary consumers, and so on. The waste products and dead bodies of organisms (known as **detritus**) provide another source of energy, as we saw at the opening of this chapter. Organisms that consume such materials are called **detritivores** or **decomposers** (see **Figure 57.2**).

Go to Media Clip 57.1

A Food Chain in Africa

Life10e.com/mc57.1

Most species in a community eat and are eaten by more than one other species, so food webs and trophic levels are necessarily oversimplified. Some organisms, called **omnivores**, feed on multiple trophic levels. Opossums, for example, are famously omnivorous. Investigators in Portland, Oregon, dissected the stomachs of road-killed opossums and found remains of mammals, birds, insects, earthworms, snails, fruits, bulbs, seeds, leaves, grass, pet food, and garbage, along with some items they couldn’t identify—a diet that would be difficult to depict in a food web.

Fewer individuals and less biomass can be supported at higher trophic levels

One important way to characterize a community is by the distribution of energy and biomass within it. The flow of energy through a community is governed by the physical laws that regulate energy transformations, foremost among which are the first and second laws of thermodynamics. Recall from **Section 8.1** that the amount of energy in the universe is constant, and that when energy is converted from one form to another, part of it becomes unavailable to do work. As **Figure 57.2** showed, energy is lost to metabolism and respiration at each trophic level.

57.3 Food Webs Show Trophic Interactions in a Community
This simplified food web for the grasslands of Yellowstone National Park includes only large vertebrates and the plants on which they depend. The arrows show who eats whom. Species whose sole source of food is plants (green arrows) are primary consumers. Carnivores that kill and eat animals (red arrows) are secondary and tertiary

consumers. Omnivores such as grizzly bears, coyotes, and ravens eat both plant and animal tissues; ravens and grizzlies also eat carrion (dashed red arrows), so these species are also detritivores.

Go to Activity 57.2 The Major Trophic Levels
Life10e.com/ac57.2

On average, only about 10 percent of the energy of one trophic level is transferred to the next, for a number of reasons:

- **Heat loss.** Organisms incorporate much of the energy they accumulate into biomass, but they use much more of it for respiration and other metabolic processes. That energy is dissipated as heat and is lost to the community.
- **Biomass availability.** Not all of the biomass in a community can be ingested. Grazers routinely miss blades of grass;

effective plant defenses prevent herbivory; prey can escape predators or leave the community.

- **Indigestibility.** Not all of the biomass ingested can be assimilated by consumers. Tree bark, for example, contains lignin and cellulose, which cannot be digested by most herbivores.

The overall transfer of energy from one trophic level to the next (which can be expressed as the ratio of consumer production to producer production) is called **ecological efficiency**.

Pyramid diagrams such as those in **Figure 57.4A** can be used to illustrate the proportions of energy transferred from each trophic level to the next and to compare those proportions among different communities. Pyramid diagrams can also be used to illustrate the amount of biomass or numbers of individuals found at each trophic level (**Figure 57.4B**). As these diagrams show, a given environment typically supports fewer individuals, less biomass, and fewer species at higher trophic levels than at lower trophic levels. Progressive energy loss through the inefficiencies of energy transfer also limits the number of trophic levels in a food chain or food web; largely for this reason, most communities support only three to five trophic levels. One conspicuous exception to this general pattern occurs in the open oceans. The phytoplankton that are the primary producers

TABLE 57.1 The Major Trophic Levels

Trophic Level	Source of Energy	Examples
Photosynthesizers (primary producers)	Solar energy	Green plants, photosynthetic bacteria, diatoms
Herbivores (primary consumers)	Tissues of primary producers	Copepods, grasshoppers, bark beetles, deer, geese, white-footed mice
Primary carnivores (secondary consumers)	Tissues of herbivores	Spiders, warblers, wolves, anchovies
Secondary carnivores (tertiary consumers)	Tissues of primary carnivores	Tuna, falcons, killer whales
Omnivores	Several trophic levels	Humans, opossums, crabs, robins
Decomposers (detritivores)	Dead tissues and waste products of other organisms	Many fungi, many bacteria, vultures, earthworms, termites

57.4 Energy and Biomass Distributions Pyramid diagrams allow ecologists to compare patterns of energy flow through trophic levels (A) and the amount of biomass present at different trophic levels in different communities (B). Biomass distribution in the open ocean differs from that in most other communities because most of the biomass is not at the primary producer level.

in this community grow and reproduce so much faster than the zooplankton and small fish that consume them that their smaller biomass, with its rapid rate of primary production, can actually support a larger biomass of primary consumers.

Productivity and species diversity are linked

Just as the diversity of a trophic level tends to be positively correlated with the amount of energy available to it, the species diversity of a community tends to be positively correlated with its productivity, up to a point (Figure 57.5). A number of factors that influence productivity vary among communities. The most obvious of these factors is energy input. The amount of solar energy reaching Earth's surface varies by latitude, as we saw in Figure 54.1. The ability of plants to photosynthesize, however, depends not only on the supply of energy from the sun but also on the supply of water and nutrients. The number of tree species across different regions of North America, for example, can be best predicted not by measuring incoming solar radiation but by measuring an ecological attribute of

those regions called **evapotranspiration**: the amount of water released from the land surface by evaporation from streams, lakes, and soil and by transpiration from plants. The annual evapotranspiration of a region is a measure of the amount of water available to the organisms living there.

The number of species in a community increases with productivity only up to a point, however. If productivity increases beyond that point, the number of species may actually decline (see Figure 57.5). Why should that be? As local productivity increases, so does the number of individuals the local habitat can support (its carrying capacity). Thus populations can grow larger, and larger population sizes should reduce the risk of species extinction. Why, then, should the number of species decrease when productivity is very high?

One hypothesis postulates that interspecific competition becomes more intense when productivity is very high, resulting in competitive exclusion of some species (see Section 56.4). This hypothesis is supported by the results of a long-term experiment at the Rothamsted Experiment Station in England, begun in 1857 and still going on. Fertilizer has been added regularly to selected plots of land to increase their productivity, and fertilized and unfertilized plots have been monitored continuously. Over 150 years, the number of plant species in the unfertilized plots has remained roughly constant, whereas the number of species in the fertilized plots has declined, supporting the premise that species diversity can decline when productivity rises.

57.5 Species Diversity Peaks at Intermediate Productivity The number of rodent species living in ecosystems of varying productivity in the Gobi Desert exemplifies a pattern in which species richness increases only up to a certain point. Beyond that point, it can actually decline with productivity.

RECAP 57.1

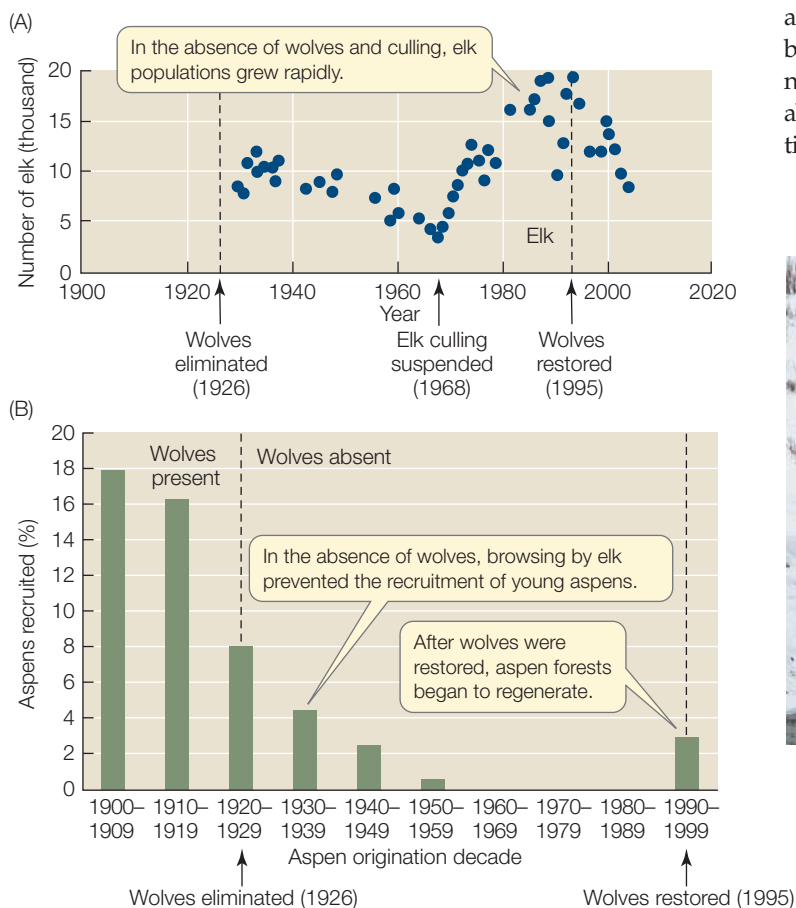

An ecological community is a group of species that coexist and interact within a defined area. Energy enters an ecological community through the primary producers and moves through the food web by means of trophic interactions.

- Explain the difference between gross primary productivity and net primary productivity. **See pp. 1189–1190 and Figure 57.2**
- Describe three trophic levels that might appear in a food web. **See pp. 1190–1191, Table 57.1, and Figure 57.3**
- What is a typical distribution of energy among the trophic levels of a community? **See pp. 1190–1191 and Figures 57.2 and 57.4**

Energy and biomass distributions primarily reflect the abiotic factors that influence the community. In the next section we will see how the interactions among species described in Chapter 56 shape community structure.

57.2 How Do Interactions among Species Influence Communities?

The antagonistic interactions described in Section 56.2, which transfer energy between trophic levels, have a strong influence

on ecological communities. But species are not identical bags of biomass through which energy flows. Species in one part of a food web can affect many other species without necessarily eating them.

Species interactions can cause trophic cascades

The interactions of a single consumer species with other species in its community can cause a progression of successive effects throughout an entire food web, a pattern called a **trophic cascade**. The reintroduction of wolves into Lamar Valley in Yellowstone National Park initiated just such a pattern.

The food web in the grasslands of Yellowstone National Park is far more complex than the “streamlined” rendition in Figure 57.3 indicates. Gray wolves in the park feed on elk, bison, and coyotes. Although they share some of these prey species with coyotes and grizzly bears, wolves exert particularly strong effects on the park community’s structure and dynamics, as demonstrated by the effects of their absence during most of the twentieth century.

By 1926, unrestricted hunting had eliminated wolves from the Yellowstone community. To prevent elk from exceeding the park’s carrying capacity, the park service culled elk herds (that is, they selectively killed some members of each herd) until 1968, when, in response to public pressure, the culls were stopped and the elk population rapidly increased (Figure 57.6A). The elk browsed aspen trees so intensely that the number of young trees recruited (added to the population) declined precipitously, and by 1960 no new trees were recruited at all (Figure 57.6B). The elk also severely browsed streamside willows, with the result that beavers, which depend on willows for food, were nearly exterminated from Lamar Valley. In regions of the park where elk were absent, however, aspen and willow trees flourished. This observation suggested that the decline of the trees in Lamar Valley was

57.6 Wolves Initiated a Trophic Cascade in Yellowstone National Park (A) Number of elk in Wyoming’s Yellowstone National Park. (B) Aspen recruitment (that is, the number of new trees becoming established) in the presence and absence of wolves.

indeed due to elk browsing rather than to climate conditions or some other factor.

In 1995, after wolves had been absent for 70 years, park managers reintroduced them to Yellowstone, and their population grew rapidly. The wolves preyed primarily on elk. The elk population of Lamar Valley dropped, and elk avoided the aspen groves, where they were especially vulnerable to wolf predation. Young aspen began to grow, willows regrew along streams, and the number of beaver colonies increased from one in 1996 to seven in 2003. Thus the presence or absence of a single predator influenced not only populations of its prey but also populations of its prey's food resource and of other species that depended on that resource.

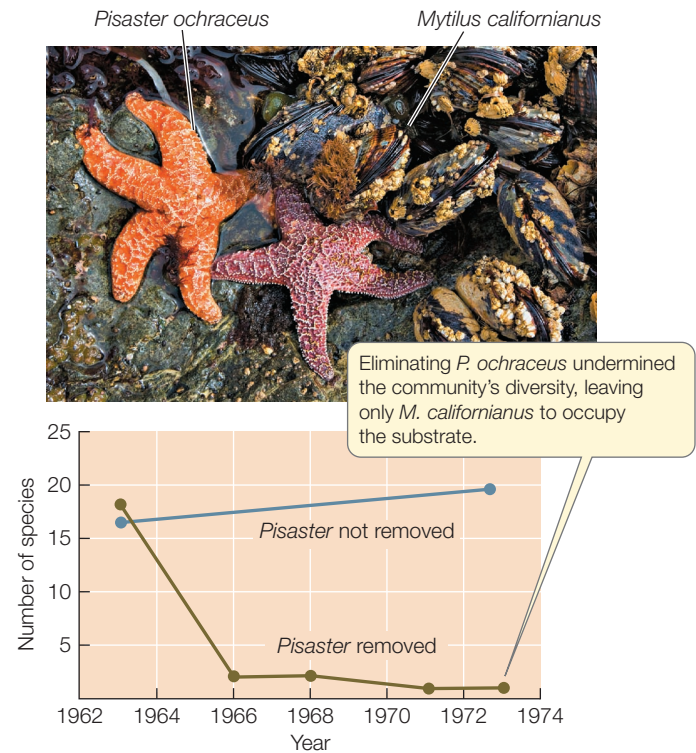

Herbivores, too, can have indirect effects on other trophic levels. The savannas of central Kenya are dominated by large grazing mammals such as zebras, eland, elephants, Grant's gazelles, giraffes, buffaloes, and hartebeests. A team of investigators used exclosures (areas protected by a barrier, such as a fence, designed to keep organisms out) to investigate the influence of these grazers on the savanna community. They created six exclosures and compared community structure within the exclosures with that in control sites where large mammals could graze freely. Over 19 months of monitoring, they found that trees, beetles, and an insectivorous lizard species were all more abundant within the exclosures. The elimination of grazing increased the abundance of trees, which in turn increased the number of beetles by providing more food and habitat, which in turn increased the number of lizards, which feed preferentially on beetles.

Trophic cascades can be initiated by the behaviors of species as well as by their diets. Beavers preferentially cut down some species of trees to build their dams; by so doing, they alter the composition of the vegetation. In addition, the beavers' activities create wetlands, meadows, and ponds that provide habitat for species that would otherwise not be able to live in the area.

Organisms that build structures that alter existing habitats or create new habitats are called **ecosystem engineers**. Beavers create new habitats by cutting down (and killing) trees and using them to dam streams and create ponds. Trees in terrestrial forests, and corals and kelp in aquatic communities, are ecosystem engineers in a different way: they modify the environment by changing their size and shape over time. For example, by becoming larger and more structurally complex as it grows, the stilt palm (*Socratea exorrhiza*) of Panama can support more than 60 species of epiphytes.

Keystone species have disproportionate effects on their communities

Architects call the single wedge-shaped stone in the center of an archway the "keystone" because it holds all the other stones in place. Ecologists thus refer to any species that exerts an influence on the other members of its community that is disproportionate to its abundance as a **keystone species**. Keystone species can influence both the number of species and the number of trophic levels in a community.

57.7 Ochre Sea Stars Are a Keystone Species (A) Along the Pacific coast of northern North America, ochre sea stars (*Pisaster ochraceus*) consume large quantities of the mussel *Mytilus californianus*, creating bare substrate that is then inhabited by a variety of intertidal species. (B) Experiments by Robert Paine and his colleagues demonstrated that when sea stars were excluded from this intertidal community, *M. californianus* outcompeted all other species for space on the substrate and eliminated the community's diversity.

The ochre sea star (*Pisaster ochraceus*), which lives in rocky intertidal zones on the Pacific coast of North America, is a good example of a keystone species. Its preferred prey is the mussel *Mytilus californianus* (Figure 57.7A). By consuming mussels, *P. ochraceus* creates bare spaces on the rocky substrate. These spaces are then taken over by a variety of intertidal species.

In a classic experiment, Robert Paine of the University of Washington demonstrated the disproportionate influence of *P. ochraceus* on species diversity by removing the sea stars from selected sites repeatedly over a 5-year period. Two major changes occurred in the areas where sea stars were absent. First, the lower edge of the mussel bed extended farther down into the intertidal zone, showing that sea stars are able to eliminate mussels completely in areas that are submerged most of the time. Second, and more dramatically, 18 species of animals and algae disappeared from the sea star removal sites. Eventually only *M. californianus*—the dominant competitor for space in the community—occupied the entire substrate (Figure 57.7B). Through its effect on competitive relationships among its prey, predation by the sea star determines how many species can thrive in its rocky intertidal community. In the absence of sea stars, *M. californianus* crowds out other organisms in a broad belt of the intertidal zone.

Species other than consumers can be keystone species. Fig trees in tropical forests, for example, produce fruits several times every year, so their fruits are abundant at times when

few, if any, other trees are fruiting. Dozens of frugivores depend on figs when no other fruits are present. Fig-eating animals include fruit bats, parrots, toucans, pigeons, flycatchers, trogons, orioles, rodents, howler monkeys, and even fish, which eat figs that fall into nearby streams. All of these animals provide prey for a diverse community of predators. Moreover, the trunks of fig trees provide habitat for several thousand species of insects, reptiles, rodents, and birds. Without fig trees, rainforest communities around the world would be profoundly diminished in terms of the number of species they contain.

RECAP 57.2

Some interactions between consumers and their resource species result in a trophic cascade of indirect effects on species at other trophic levels. A keystone species has effects on its community that are disproportionate to its abundance.

- Describe an example of a consumer whose interactions with other species cause indirect effects across trophic levels. [See p. 1194](#)
- What are some of the ways in which keystone species can affect other species in their communities? [See p. 1194](#)

We have seen how certain keystone species influence the species composition of their communities. But a simple count of species is only one measure of community diversity. The next section will look more closely at the different ways in which ecologists measure species diversity.

57.3

What Patterns of Species Diversity Have Ecologists Observed?

Communities clearly vary in their diversity, both geographically, on scales ranging from local to global, and over time, on scales ranging from a day to centuries. Comparing the diversity of two or more communities can be challenging because diversity has many different components depending on the scale at which it is measured. In some cases it is important to measure species diversity within a single community or habitat, but it can also be useful to measure diversity across an entire region, encompassing a range of communities or habitats.

Diversity comprises both the number and the relative abundance of species

The most straightforward way to quantify the diversity of a community is to count the number of species present in a sample. This number is the **species richness** of the community. The larger the area that is sampled, the greater the likelihood that rare species in the community will be found, and the more accurate the resulting assessment of its species richness will be.

To say that two communities of the same size have the same species richness tells only part of the story, however. How abundant each species is in the community also affects diversity. This aspect of diversity—the distribution of abundances of individuals across species—is called **species evenness**. Imagine that we take samples of 12 individuals in each

57.8 Species Richness and Species Evenness Both Contribute to Diversity These two hypothetical mushroom communities are the same size (12 individuals) and have the same species richness (four species), but community A has a more even distribution of species and is thus more diverse than community B.

of two different communities. Our sample from community A contains 3 individuals of each of four species (an even distribution of individuals). Our sample from community B, however, contains 9 individuals of one species and only 1 individual of each of the other three species (an uneven distribution). Even though the species richness of the two communities is the same (four), community B is less diverse because the less abundant species are encountered infrequently compared with the single most abundant species (**Figure 57.8**). Thus estimates of diversity should account for both species richness and species evenness.

A study of diversity patterns in an agricultural region of southern England demonstrates how measures of diversity can be applied at different spatial scales. Investigators sampled plants and macroinvertebrates in three types of freshwater communities—rivers, ponds, and ditches—in this area of English countryside. Rivers had high species richness, but most rivers in the area contained the same assortment of species. In contrast, the ponds displayed a wide range of variation in species richness. Thus the ponds contributed more to the overall diversity of the area than the rivers did because they contained

57.9 Latitudinal Gradients in Diversity Among swallowtail butterflies (Papilionidae), species diversity decreases with latitude both north and south of the equator. Similar latitudinal gradients of diversity have been observed in many other taxa.

more unique or rare species. Surprisingly, the ditches, many of which contained water for only a short time, had the lowest species richness of the three community types, but many of the species in the ditches were found nowhere else in the area, including insects that live only in temporary bodies of water (including a very rare water beetle). Ponds and ditches, despite being relatively species-poor, contributed disproportionately to regional diversity because the few species they did support were found nowhere else in the region. Partitioning diversity within a community, between communities, and across an entire region in this way can provide insights into the ecological characteristics of the species making up those communities as well as the processes by which those communities were assembled.

Ecologists have observed latitudinal gradients in diversity

Diversity can be measured at a wide range of scales, but the broader the scale at which it is measured, the more difficult it can be to understand the ecological process underlying the differences observed. Understanding diversity at a global scale has proved to be a challenge.

About 200 years ago, the German explorer and naturalist Alexander von Humboldt spent 5 years traveling around Latin America. He remarked in the account of his voyages that “the nearer we approach the tropics, the greater the increase in the variety of structure, grace of form, and mixture of colors, as also in perpetual youth and vigour of organic life.” Humboldt would not have been surprised to learn that, if he had sailed toward the poles, the diversity he observed would have decreased. These latitudinal gradients in diversity have been observed repeatedly in both hemispheres and in a wide variety of taxa, including birds, mammals, flowering plants, and insects (Figure 57.9).

Although most ecologists agree that latitudinal gradients in diversity exist, there is less consensus as to why they exist. At least four hypotheses have been advanced to account for latitudinal gradients in diversity:

- The *time hypothesis* argues that over evolutionary time, organisms in tropical regions have had more time to diversify under relatively stable climate conditions than have those in more temperate regions.
- The *spatial heterogeneity hypothesis* suggests that tropical regions have higher spatial heterogeneity—more different types of microclimates, vegetation, soils, and so forth—and thus contain more distinct habitats and many more species.
- The *specialization hypothesis* attributes latitudinal gradients to greater interspecific competition in the tropics, which leads to narrower realized niches (see Figure 56.15).
- The *predation hypothesis* proposes that predation intensity is greater in the tropics. Where predation is high, it argues, prey populations are held to levels so low that interspecific competition never comes into play, and rare species can persist.

Corroborative evidence can be found for each of these hypotheses, varying with taxon, locality, and scale, and not all of the hypotheses are mutually exclusive. It may be that multiple factors are responsible for this widespread ecological pattern.

The theory of island biogeography suggests that immigration and extinction rates determine diversity on islands

While latitudinal diversity gradients prevail on a global scale, other factors influence species diversity at smaller spatial scales. For example, small islands tend to have fewer species

WORKING WITH DATA:

Latitudinal Gradients in Pitcher Plant Communities

Original Paper

Buckley, H. L., T. E. Miller, A. Ellison, and N. J. Gotelli. 2003. Reverse latitudinal trend in the species richness of an entire community at two spatial scales. *Ecology Letters* 6: 825–829.

Analyze the Data

In 2003 Hannah Buckley and several colleagues examined the diversity of species present in the community of water-filled leaves—pitchers—of *Sarracenia purpurea* (see Figure 57.1A). The researchers determined the relative abundances of all species of invertebrates (including insect larvae), heterotrophic protists (protozoa), and bacteria present in each of 20 pitcher plants collected at each of 39 sites that spanned the plant's entire north–south range. They summarized the data at two scales: as the average number of species per site (the site-wide scale) and as the average number of species per pitcher at each site (the pitcher scale). Their data are plotted in the graphs at the right.

QUESTION 1

Overall, does this community display a typical diversity gradient with latitude? Of the individual taxa, which ones depart from the typical diversity gradient?

QUESTION 2

The top predator in this system is the larva of the mosquito *Wyeomyia smithii*, which filter-feeds on bacteria and protozoans. This species is significantly more abundant at low latitudes (i.e., farther south in the Northern Hemisphere) than at high latitudes. How might the abundance of a top predator explain the pattern observed by these investigators?

QUESTION 3

Do you think *Wyeomyia smithii* is a keystone species? Why or why not?

Go to **BioPortal** for all **WORKING WITH DATA** exercises

than large islands, irrespective of latitude (Figure 57.10). The biologist Edward O. Wilson was struck by this **species–area relationship**, which he encountered through his exhaustive collection of ant species from all over the world.

With Robert MacArthur, Wilson developed the theory of **island biogeography**. They based their theory on just two processes: the immigration of new species to an island and the extinction of species already present on that island (Figure 57.11A). The premise of island biogeography is that the number of species on an island represents a balance, or equilibrium, between the rate at which species immigrate to and colonize the island and the rate at which resident species go locally extinct.

The rate of immigration is determined in part by the number of species in the source area providing the immigrants, known as the **species pool**. In the case of oceanic islands, the species pool comprises all the species on the nearest land mass (usually a continent). Not all species that reach the island will persist there, however. The more species there are on an island, the greater the likelihood that there will be competition for limited resources, and the higher the likelihood that any of the species on the island will go extinct. Therefore at some point the number of species arriving from

57.10 The Species–Area Relationship E. O. Wilson and Robert MacArthur plotted the number of species of reptiles and amphibians against the size of several islands in the Antilles of the Caribbean. Larger islands consistently contained more species, regardless of latitude, a fact these scientists incorporated in their theory of island biogeography.

57.11 MacArthur and Wilson's Theory of Island Biogeography

(A) The rate of arrival of new species and the rate of extinction of species already present determine the equilibrium number of species on an island. These rates and the eventual equilibrium numbers are affected by the size of the island (B) and by the island's distance from the mainland (C). For simplicity these rates are depicted as linear, but in reality immigration and extinction rates tend to be curvilinear.

the source area and the number of resident species going extinct should balance, and the number of species should remain stable at this balance point, referred to as the equilibrium number of species.

Rates of immigration and extinction, and thus the equilibrium number of species on an island, are influenced by two other factors:

- **The size (area) of the island.** The smaller the island, the fewer resources it provides, the greater the potential for competition, and the higher the extinction rate will be (Figure 57.11B). Larger islands provide greater habitat diversity and can sustain larger populations (which tend to have lower extinction rates than small populations).
- **Distance of the island from the species pool.** The farther the island is from the source of immigrants, the lower the immigration rate—the rate at which new species arrive—will be (Figure 57.11C).

Between 1966 and 1969, Wilson and his student Daniel Simberloff conducted an ingenious experiment to test the theory

of island biogeography (although given concerns over environmental impacts, this experiment might not have been approved today). Simberloff and Wilson identified four small, isolated clumps of red mangrove (*Rhizophora mangle*), all approximately the same size (11–12 meters in diameter), in the Florida Keys. These mangrove islands were small enough to allow an accurate count of the arthropod species on each one. They were also small enough for the research team to enclose each island in a tent and gas it with methyl bromide to kill all the arthropods. After this defaunation, Simberloff and Wilson monitored and tracked recolonization of the islands by arthropods (Figure 57.12). After 2 years, species richness on all but the farthest island was close to what it was before defaunation. This observation is consistent with the idea that the number of species on the islands prior to defaunation represented an equilibrium number of species.

The theory of island biogeography can be applied equally well to **habitat islands**—isolated patches of suitable habitat surrounded by extensive areas of unsuitable habitat. Thus a pond in the English countryside or a forest surrounded by housing subdivisions may acquire an equilibrium number of species in much the same way an oceanic island does. The theory of island biogeography also has important applications for the conservation of endangered species. As habitat islands decrease in size because of human encroachment, more and more species become vulnerable to population declines, especially those that require large areas in order to live and breed successfully. Even more broadly, the processes of immigration and extinction contribute to determining community composition at continental scales.

RECAP 57.3

Measures of species diversity encompass both species richness and species evenness. Species diversity is highest in the tropics, decreasing at higher latitudes. Island biogeography theory states that species diversity on an island or other isolated habitat represents a balance between immigration and extinction rates.

- What is the difference between species richness and species evenness? See p. 1195 and Figure 57.8
- Explain how scale can influence estimates of diversity. See pp. 1195–1196
- What factors influence the equilibrium number of species on an island, according to the theory of island biogeography? See pp. 1197–1198 and Figure 57.11

The composition of a community is dynamic: as we have seen, it can change over time and space. Processes of change such as immigration to and extinction on islands are generally predictable and consistent. But community composition can change dramatically in response to less predictable forces as well.

INVESTIGATINGLIFE

57.12 The Theory of Island Biogeography Can Be Tested

By experimentally removing all the arthropods on four small mangrove islands of equal size but different distance from the mainland, Simberloff and Wilson were able to observe the process of recolonization and compare the results with the predictions of island biogeography theory.

HYPOTHESIS If mangrove islands are populated by an equilibrium number of species, then the rate at which they will accumulate species after defaunation will decrease with distance from a mainland source of colonists, as will their eventual species richness.

- Method**
1. Census the terrestrial arthropods on 4 small mangrove islands of equal size (11–12 m diameter) but different distance from a mainland source of colonists.
 2. Erect scaffolding and tent the islands. Fumigate with methyl bromide (a chemical that kills arthropods but does not harm plants).

3. Remove tenting. Monitor recolonization for the following 2 years, periodically censusing terrestrial arthropod species.

Results Recolonization was fastest on the closer islands, slowest on the one farthest from the mainland. Two years after defaunation, each island had about the same number of species it had before the experiment.

CONCLUSION The data support the theory that species richness on islands represents a dynamic balance between colonization and extinction rates.

57.4 How Do Disturbances Affect Ecological Communities?

An ecological **disturbance** is a disruption in a community caused by a discrete external force, often abiotic in nature. Disturbances may remove some species from a community but may open up space and resources for other species.

The magnitude of a disturbance's effects varies enormously. Some disturbances are limited to small areas—for example, a log carried by waves may crush algae and animals attached to rocks in an intertidal community. In contrast, hurricanes, forest fires, and volcanic eruptions affect communities over hundreds or thousands of hectares. Although small-scale disturbances are far more frequent, a few large-scale events may be responsible for most of the changes in a community. A single hurricane, for example, may fell more trees than several years of “normal” storms, and the movements of a glacier change community composition across millennia.

A community's history of disturbance may explain patterns of species diversity that would otherwise be puzzling. The Province Islands, located just above the Antarctic Circle in the South Indian Ocean, provide an example. The climate of these islands is cool, with average temperatures above freezing for only 6 months of the year; precipitation is high, and gale force winds are common. The vegetation is primarily tundra. South African entomologist S. L. Chown, an expert on life in the Antarctic, compared the insect faunas on the four largest of these islands and found that the two largest, Marion and Kerguelen, housed fewer arthropod species (16 and 22 species, respectively) than the significantly smaller Cochons and Possessions (26 and 38 species). Why do the species diversity patterns on these islands fail to conform to the theory of island biogeography? One possible explanation lies in their different disturbance histories. The two largest islands were once covered by glaciers and thus experienced considerably more disturbance than did the two smaller islands.

Succession is the predictable pattern of change in a community after a disturbance

How does a community recover from a disturbance, particularly one as massive as a glacier? The pattern of change in community composition following a disturbance is known as **succession**. The most common type of succession is **directional succession**, which is characterized by an orderly (or at least predictable) progression

57.13 Primary Succession As the community occupying a glacial moraine at Glacier Bay, Alaska, changes from an assemblage of pioneer plants such as *Dryas* to a spruce forest, soil depth increases and nitrogen accumulates in the soil.

 **Go to Animated Tutorial 57.2**
Primary Succession on a Glacial Moraine
Life10e.com/at57.2

of community assemblages. Species come and go until a particular community—one that is capable of perpetuating itself under the local climate and soil conditions—persists for a relatively long time. This persistent stage is called the **climax community**.

Directional succession is easiest to observe after a disturbance strips away all preexisting living organisms and exposes a bare substrate. The type of directional change that occurs under these circumstances is known as **primary succession**. Glaciers (see Figure 1.16), volcanic activity, and in some cases, floods can initiate primary succession.

Primary succession can be seen in the successive changes in plant growth form and community composition in the wake of the retreat of the glacier in Glacier Bay, Alaska, over the last 200 years (Figure 57.13). The glacier scraped the landscape down to bare rock and left a series of moraines—gravel deposits dropped where the glacial front was stationary for a number of years. No human observer was present to measure changes over the entire 200-year period, but ecologists have inferred the temporal pattern of succession by studying the vegetation on moraines of different ages. The youngest moraines, closest to the current glacial front, are populated with bacteria, fungi, and photosynthetic microorganisms that can support themselves on bare rock. Slightly older moraines farther from the glacial front are home to lichens, which break down rocks and, when they die, decompose and contribute to the buildup of soil. Mosses and a few species of shallow-rooted herbs such as mountain avens (*Dryas octopetala*) become established and contribute to soil-building as they die and decompose. Still farther from the glacial front, successively older moraines have deeper soil layers that support shrubby willows, alders, and spruces.

Nitrogen is virtually absent from glacial moraines, so the plants that grow best on recently formed moraines at Glacier Bay are *Dryas* and alders (*Alnus*), both of which have nitrogen-fixing bacteria in nodules on their roots (see Figure 36.7B). Nitrogen fixation by these plants improves the soil so that spruces can grow. Spruces then outcompete and displace the early colonists. If the local climate does not change dramatically, a climax community dominated by spruce trees is likely to persist for many centuries on old moraines at Glacier Bay.

Directional succession following a disturbance that some organisms, particularly those in the soil, survive is called **secondary succession**. Secondary succession is often initiated by human activities (such as the clearing of a forest) as well as by natural disasters (such as storms and fires). Generally easier to monitor than primary succession, secondary succession also tends to occur more frequently and progress more rapidly.

A typical sequence of secondary succession in eastern North America begins when forested land that had been cleared for agriculture is abandoned (Figure 57.14). Because the soil is left intact, abandoned farmland provides an excellent environment for plants to colonize. The first plants to appear in old agricultural fields are fast-growing annuals such as pigweed, ragweed, and lamb's-quarter. These plants grow from seeds that have persisted in a dormant state in the soil since before the land was farmed, awaiting the opportunity to germinate. A single individual lamb's-quarter (*Chenopodium album*) can produce more than 150,000 tiny seeds. These pioneer species are quickly replaced by biennials and perennials that are stronger competitors for resources, such as milkweed, goldenrod, and thistles. The seeds of many of these plants have mechanisms for long-distance dispersal that allow them to colonize newly cleared sites. Milkweed seeds, for example, come equipped with a silky "parachute" that catches the wind and allows them to travel long distances. Eventually shrubby plants such as dogwood, eastern red cedar, and sumac become established, followed by tree species such as cottonwood, cherry, and red maple. Ultimately, shade-tolerant tree species whose seedlings can survive the shady conditions under the established trees, including beech and sugar maple, dominate the landscape. The beech-maple forest is the climax community for much of the region.

57.14 Secondary Succession Land that was once an agricultural field ultimately supports a long-lasting climax community characterized by shade-tolerant trees.

Directional succession, irrespective of where it takes place, is characterized by certain trends. In general, the pioneer species of early successional stages tend to be good dispersers with high rates of increase (*r*-strategists; see Section 55.4). Early stages of succession are characterized by high productivity and simple food webs; most nutrients are present in detritus or in the soil. As succession proceeds, nutrients accumulate in living biomass, food webs become more complex, and abiotic sources of nutrients become less important. Species typical of late successional stages tend to be good competitors with relatively low intrinsic rates of increase (*K*-strategists).

Both facilitation and inhibition influence succession

To some extent, the progress of succession depends on the activity of successive colonists, each of which modifies the environment in such a way as to facilitate colonization by other species. Predators are unlikely to colonize a habitat with no prey species, nor can primary consumers exist before plants are established. The fixation of nitrogen by *Dryas* and alders, which allows spruces to become established in Glacier Bay (see Figure 57.13), is an example of such **facilitation**.

Although secondary succession is often described in terms of changes in plant species composition, colonization by plants is actually facilitated by heterotrophs. Many of the first organisms to arrive on bare soil after a disturbance are detritivores, which process dead organic matter and release nutrients (especially nitrogen), thus facilitating the establishment of plants. In a study of intensively burned 20-year-old pine plantations in northern Germany, the first organisms to colonize these burned forests were algae, slime molds, liverworts, mosses, and mushrooms. These were followed by algae-feeding flies, fungus-feeding beetles, and moss-feeding springtails. Flowering plants such as fireweed moved in, at which point leaf-feeding insects appeared, soon followed by predaceous ground beetles and wolf spiders. Even in the corpse communities described at the opening of this chapter, early colonists can make resources available for subsequent colonizers: some spider beetles, for example, cannot feed on rotting flesh directly, but

rather feed on the excrement of the early flesh-eating colonizers.

In other cases the effect of early colonists does not facilitate but rather inhibits colonization by other species. The roots of some old-field species such as goldenrod and thistle exude chemicals that inhibit the germination and growth of potential competitors. Eventually, when these plants grow old and die, other plant species can become established. Similarly, in rocky intertidal communities, when wave action turns over boulders and clears rock surfaces, the green alga *Ulva* colonizes the cleared spaces quickly and efficiently, preventing colonization by the slower-growing perennial red algae. Certain crab species then selectively graze on *Ulva*, helping to undermine this inhibition and thus promoting the establishment of the red algae that dominate the community in later stages.

Cyclical succession requires adaptation to periodic disturbances

Some forms of disturbance recur with regularity, even if their recurrence is not always predictable. Such recurrent disturbances are associated with a pattern called **cyclical succession** because the climax community depends on the periodic disturbances in order to persist. The lodgepole pine (*Pinus contorta*) forests of southern Oregon, for example, are maintained by periodic forest fires (Figure 57.15). In this fire-adapted community, fires return nutrients to the soil in the form of burned organic matter and thus provide favorable conditions for seed germination. The cones of lodgepole pines are sealed shut by resins; only when they are subjected to high temperatures that melt the resins do they open and release their seeds.

57.15 Some Communities Are Adapted to Disturbance Forest communities dominated by lodgepole pine (*Pinus contorta*) are adapted to periodic fires. Fire removes mature trees weakened by pest infestation, revitalizes the soil, and provides favorable conditions for seed germination and new growth.

Lodgepole pine trees are attacked by the mountain pine beetle (*Dendroctonus ponderosae*) and are also prone to infection by the fungus *Phaeolus schweinitzii*, which causes the roots and heartwood of the trees to rot. Trees that have lived long enough to experience and be scarred by a fire are much more likely to become infected by the fungus than are trees that have not been scarred. Fungus-infected, weakened trees are preferentially attacked by beetles. After a beetle outbreak, in which many mature, fire-scarred trees are killed, the dead trees serve as potential fuel for a fire that will free up their nutrients for use by the remaining trees as well as new seedlings.

Heterotrophic succession generates distinctive communities

Plants play a vital role in most patterns of succession because, as autotrophs, they are the source of energy for the other organisms in the community. Successional changes, however, can take place without the participation of plants. Detritus-based communities—found in dung, dead plants, and carrion—undergo a series of changes known as **heterotrophic succession**. In these communities, energy resources are greatest when the habitat first becomes available to colonists and are depleted as succession takes place. There is no mechanism, such as photosynthesis, for generating more energy. Thus in contrast to most other forms of succession, biomass and species diversity decrease over time because the resource base declines. In addition, these temporary habitats are not really self-contained, so predators, which do not have to confine themselves to one dead body to live out their lives, can outnumber primary consumers (detritivores, in these communities), in apparent violation of the laws of thermodynamics.

RECAP 57.4

Ecological disturbances may remove some species from a community but may open up space and resources for other species. Ecological succession—a predictable pattern of change in community composition—typically follows a disturbance.

- How do primary succession and secondary succession differ? **See p. 1200 and Figures 57.13 and 57.14**
- Describe some ways in which early colonists facilitate or inhibit colonization by the species that follow them in a pattern of succession. **See p. 1201**

Now that we have seen how communities change in composition over time, let's look at what allows certain communities (such as climax communities) to persist over time and withstand disturbance with little change. In this context we will return to diversity as an important arbiter of community stability.

57.5 How Does Species Richness Influence Community Stability?

Up to a point, higher productivity favors higher species richness, as we saw in Section 57.1. Does species richness, in turn,

influence productivity? And how do both of those properties influence community stability? We might expect species richness to enhance productivity because no two species in a community use resources in exactly the same way (as illustrated in Section 56.4 by the principle of competitive exclusion), so a mixture of more species might result in a more complete use of the available resources. Moreover, if environmental conditions should change, a species-rich community is more likely to contain some species that can persist under the new conditions. Thus a species-rich community should be more stable—that is, it should change less over time in either productivity or species composition—than a species-poor community.

Species richness is associated with productivity and stability

To test the hypothesis that species-rich communities are more stable than species-poor communities, David Tilman and his colleagues at the University of Minnesota cleared 120 outdoor plots, in which they planted grasses in mixtures ranging from 2 to 22 grass species. At the end of each growing season, they measured total plant cover (a measure of grass biomass, and thus of net primary production) and the population densities of all the grasses in each plot. Over a period of 11 years, which included a serious drought, the plots with more species were more productive (**Figure 57.16A**), and their productivity was less variable from year to year. These findings were consistent with the hypothesis that species richness promotes productivity and keeps productivity stable. Moreover, in the plots with greater species richness, soil nitrogen was used more efficiently (**Figure 57.16B**). However, the population densities of *individual* species in the plots were not stable over the years (regardless of a plot's species richness) because different species performed better during drought years and wet years. In other words, higher species richness increased the stability of productivity in the plots, but not the stability of their species composition.

Researchers continue to debate whether species diversity is responsible for maintaining stability or is simply correlated with stability. This question is important because many of the alterations humans have made in the structure of natural communities have reduced their species richness, and many of these human-altered communities—notably agricultural communities—are notoriously unstable.

Diversity, productivity, and stability differ between natural and managed communities

Although ecologists have been debating the relationships among species richness, productivity, and stability for only a few decades, humans have been experimenting with those relationships, albeit inadvertently, for millennia—since plants were domesticated and agriculture was invented. Since the dawn of agriculture, crops have been susceptible to diseases and insect outbreaks: massive (often sudden) increases in populations of species that destroy or damage crops.

The practice of growing crops as **monocultures**—plantings of a single crop species—is one reason why managed

(A) Plant cover

(B) Efficiency of nitrogen use

57.16 Species Richness Enhances Community Productivity

Tilman and colleagues cultivated a total of 120 grassland plots, containing from 2 to 22 grass species, for 11 years. (A) Total plant cover (a measure of grass biomass, and thus of net primary production). (B) The amount of nitrogen remaining in the soil is a measure of resource use efficiency.

agricultural communities are particularly unstable. Most farmers have little tolerance for the presence of any potential competitors for their crops and actively eliminate weeds (and the herbivore species that live with them) from their fields. Thus a typical agricultural community has very low species diversity. So the answer to the question of whether diversity causes or is merely correlated with stability may be sought in modern farming practices. The predisposition of agricultural communities to play host to outbreaks may well result from human influences on community structure.

For the last 20 years, ecologists have been using traditional subsistence agricultural plots as experimental models for testing the relationships between diversity and stability. Throughout the world, many farmers with small land holdings grow multiple crops on the same plot. In Costa Rica, for example, farmers often grow corn together with sweet potato. Such corn–sweet potato dicultures contain fewer sweet potato pests and many more parasitoid wasps (which feed on those pests)

than sweet potato monocultures do. The wasps feed on the corn pollen, and the tall corn plants act as a structural barrier, shade plant, and source of disruptive chemical signals that interfere with the ability of the sweet potato pests to find their host plants.

In recent years such applications of community ecology have been paying dividends. Although monoculture is overwhelmingly the dominant agricultural practice, polycultures are under development for agricultural production systems as varied as carp and shrimp farming, vermicomposting (raising worms for compost), and biofuel feedstock production.

RECAP 57.5

Communities with higher species diversity tend to be more productive and more stable than less diverse communities because they use resources more efficiently. The instability of modern agricultural monocultures suggests that diversity results in stability.

- What relationships have ecologists observed between species diversity, community productivity, and community stability? [See p. 1202 and Figure 57.16](#)
- Describe some agricultural practices that might result in more stable ecological communities. [See pp. 1202–1203](#)

How do the insect species in a corpse community influence one another's ability to survive?

ANSWER

The animal communities in decomposing corpses consist primarily of insects, but their exact composition varies with the factors that influence the rate and nature of decomposition: climate, season, and the condition of the body, including whether it is immersed or buried, wrapped or exposed. Typically, immediately after death blow flies, bluebottle flies, and house flies arrive to lay eggs. As a detectable odor develops, other flies, including green-bottles and flesh flies, arrive. Fat breakdown, with its accompanying release of volatile fatty acids, attracts a range of carrion-feeding beetles. As proteins decompose, cheese skippers can colonize. Other species have less interest in the corpse than in the corpse-eaters: rove beetles prey on the maggots that develop from the flies' eggs. During decay, skin beetles, hide beetles, and clothes moths (which can feed on the keratin in mammalian hair) dominate. In the final stages of decomposition, spider beetles and other scavengers arrive to feed on the excrement and shed exoskeletons of the insects that have been consuming the corpse. This succession varies tremendously with climate and geography, but within any particular region it is sufficiently predictable that it is admissible in court as evidence of the time of death.

57.1 What Are Ecological Communities?

- A **community** is a group of species that coexist and interact within a defined area.
- **Gross primary productivity (GPP)** is the rate at which the **primary producers** in a community turn solar energy into chemical energy via photosynthesis. **Net primary production** represents the energy incorporated into primary producer **biomass**. **Review Figure 57.2, ACTIVITY 57.1**
- A **food web** is a diagram of the feeding relationships in a community. **Review Figure 57.3**
- The organisms in a community can be divided into **trophic levels** based on the energy sources they use. Primary producers get their energy from sunlight; **primary consumers** get their energy by eating primary producers; **secondary consumers** get their energy by eating primary consumers; and so on. **Review Table 57.1, ACTIVITY 57.2**
- Organisms that consume the dead bodies of other organisms or their waste products are called **detritivores** or **decomposers**. **Omnivores** are organisms that feed at multiple trophic levels.
- **Ecological efficiency** is the overall transfer of energy from one trophic level to the next. Pyramid diagrams illustrate the proportions of energy or biomass that flow to each successive trophic level. **Review Figure 57.4**
- Species diversity tends to increase with productivity up to a point; however, if productivity increases beyond that point, species diversity may decline. **Review Figure 57.5**

57.2 How Do Interactions among Species Influence Communities?

- The interactions of a consumer with other species can result in a **trophic cascade**: a series of indirect effects across successive trophic levels. **Review Figure 57.6**
- Organisms that build structures that create habitat for other species are known as **ecosystem engineers**.
- **Keystone species** have an influence on their community that is disproportionate to their abundance. **Review Figure 57.7**

57.3 What Patterns of Species Diversity Have Ecologists Observed?

- Species diversity encompasses **species evenness** as well as **species richness**. **Review Figure 57.8**

- Species diversity can be measured at multiple spatial scales: within a single community or habitat, or over a range of communities in a geographic region.
- Latitudinal gradients in diversity, with the greatest diversity at low latitudes, have been observed in many taxa. **Review Figure 57.9**
- According to the theory of **island biogeography**, the equilibrium number of species on an island represents a balance between the rate at which species immigrate to the island from the mainland **species pool** and the rate at which resident species go extinct. **Review Figure 57.11, ANIMATED TUTORIAL 57.1**

57.4 How Do Disturbances Affect Ecological Communities?

- A **disturbance** is a disruption in a community caused by a discrete external force, often abiotic in nature.
- **Succession** is a predictable pattern of change in community composition following a disturbance. In **directional succession**, species come and go in a predictable sequence until a **climax community** forms and persists for an extended time.
- **Primary succession** begins on sites that lack living organisms. **Secondary succession** begins on sites where some organisms have survived a disturbance. **Review Figures 57.13, 57.14, ANIMATED TUTORIAL 57.2**
- In any pattern of succession, species that become established may facilitate or inhibit colonization by other species.
- In **cyclical succession**, the climax community is maintained by periodic disturbances.
- **Heterotrophic succession** in detritus-based communities does not rely on photosynthesis and therefore differs in a number of ways from other types of succession.

57.5 How Does Species Richness Influence Community Stability?

- Species-rich communities use resources more efficiently, and thus tend to vary less in productivity, than do less diverse communities. **Review Figure 57.16**
- **Monocultures** are subject to pest outbreaks, whereas agricultural communities containing greater species diversity tend to be more stable.

CHAPTER REVIEW

REMEMBERING

- An ecological community is
 - a group of species that coexist and interact within a defined area.
 - a group of species that coexist and interact in an area together with the abiotic environment.
 - all the species in an area that belong to a particular trophic level.
 - all the species that are members of a local food web.
 - All of the above
- A trophic level consists of those organisms
 - whose energy has passed through the same number of steps to reach them.
 - that use similar foraging methods to obtain food.
 - that are eaten by a similar set of predators.
 - that eat both plants and other animals.
 - that compete with one another for food.
- Net primary production is
 - the total amount of photosynthesis in a community.
 - the total amount of primary producer biomass available for consumption by heterotrophs.
 - the total amount of biomass produced by all autotrophs and heterotrophs in a community.
 - the total amount of biomass consumed by heterotrophs.
 - gross primary productivity minus secondary productivity.
- Pyramid diagrams of energy and biomass distribution for forests and for grasslands differ because
 - forests are more productive than grasslands.
 - forests are less productive than grasslands.
 - large mammals avoid living in forests.
 - wood presents more nutritional challenges to herbivores than grasses do.
 - grasses grow faster than trees.
- The theory of island biogeography
 - predicts that the equilibrium number of species on an island is a balance between the rate of immigration of new species and the rate of extinction of resident species.
 - predicts that the rate of immigration of new species will decline with island distance from the mainland species pool.
 - predicts that the rate of extinction of resident species will decrease as island size increases.
 - applies to isolated habitat patches as well as to oceanic islands.
 - All of the above
- Which of the following events is *not* followed by primary succession?
 - A glacier recedes.
 - A volcano erupts.
 - A fire destroys a forest.
 - A hurricane creates a bare-sand beach.
 - All of these disturbances are followed by primary succession.
- Early stages of succession are characterized by
 - species that are good dispersers.
 - species with high rates of reproduction.
 - simple food webs.
 - nutrients that are available primarily from detritus and abiotic sources.
 - All of the above

UNDERSTANDING & APPLYING

- Recent analyses of human gut flora using genomic methods have revealed tremendous microbial diversity, including many previously unknown species (see Figure 26.21). This microbial diversity has effects on human health. Describe the ecological methods you could use to investigate (a) how microbial diversity varies between individuals or across populations; and (b) which particular microbes might be keystone species or ecosystem engineers.
- Jan Beck and Ian Kitching examined patterns of hawk moth diversity in the 113 islands of Thailand and mainland Malaysia. How do the findings of their study as summarized in the figure below relate to the theory of island biogeography?

ANALYZING & EVALUATING

10. Marek Sammul, Lauri Oksanen, and Merike Mägi investigated the effect of productivity on species richness in 16 different plant communities in western Estonia and northern Norway. When they removed one perennial species (the goldenrod *Solidago virgaurea*) from these communities, they found that its competitors, particularly the grass *Anthoxanthum odoratum*, increased in biomass, most noticeably in communities with high productivity (where living plant biomass was greater than 200 g/m²). In less productive communities, such increases could not be detected. How might interspecific competition lead to a decrease in species richness at high levels of productivity? What other hypotheses might explain this puzzling relationship, and how would you test them?
11. Sea lampreys (*Petromyzon marinus*) are parasitic fish that fasten onto the bodies of host fish with their disc-shaped mouths and remain attached for long periods, feeding on the host's blood and other body fluids (see Figure 33.11B). This invasive species was responsible for reducing populations of sport fish in the Great Lakes, and consequently has been the target of many extermination campaigns. Recent studies, however, have revealed that *P. marinus* spawns in fast-moving freshwater streams, where these fish build elaborate nests by burrowing and by moving stones around, to create nesting mounds. While they are nesting, sea lampreys do not parasitize other fish. Also, when adult lampreys die, their decomposing remains help restore nutrients to freshwater habitats. Later in the season, salmon and brook trout move from the ocean to freshwater streams; they spawn in the same habitats as the lampreys and are known to use abandoned lamprey nests with great success. Given all this, should lampreys be eliminated as damaging parasites of game fish, or should they be encouraged as ecosystem engineers? What other kinds of information might you need to decide on an ecologically sound lamprey management strategy?

- 58.2** How Do Materials Move through the Global Ecosystem?
- 58.3** How Do Specific Nutrients Cycle through the Global Ecosystem?
- 58.4** What Goods and Services Do Ecosystems Provide?
- 58.5** How Can Ecosystems Be Sustainably Managed?

HOW CAN A CORNFIELD in Illinois, 1,500 kilometers from the nearest ocean, affect the price of sushi? When farmers in the Midwest apply chemical fertilizers to their fields, nitrogen and phosphorus from those fertilizers are dissolved in rainwater and washed into streams, which carry them into the Mississippi River. The river water eventually reaches the Gulf of Mexico, where the enormous inputs of dissolved nitrogen and phosphorus nourish explosive blooms of floating photosynthetic organisms (phytoplankton), including algae.

During the day, phytoplankton photosynthesize and produce oxygen. At night, however, they take up oxygen from the water to carry out cellular respiration. When these short-lived organisms die, their bodies sink to the bottom, where bacterial decomposition further depletes oxygen. This process results in a state of hypoxia (the reduction of dissolved oxygen to levels below 2 milligrams per liter of water), suffocating other organisms and creating a “dead zone.” There are more than 140 coastal dead zones around the world. The one in the northern Gulf of Mexico, which has been mapped since 1985, is among the largest, spanning an area the size of New Jersey.

The Atlantic croaker (*Micropogonias undulatus*) lives along the coasts of eastern North America and the Gulf of Mexico. These bottom-feeding fish, which consume invertebrates, can reach 30 centimeters in length when mature. Their white, firm flesh is used in imitation crabmeat, or surimi, a popular ingredient in sushi. But recently croakers in the dead zone have

The Gulf Dead Zone High concentrations of nitrogen and phosphorus in the runoff from agricultural lands in the U.S. interior are carried by the Mississippi River to the Gulf of Mexico. This nutrient enrichment of Gulf waters creates a “dead zone” in which many aquatic organisms cannot survive.

experienced strange symptoms that may forecast a decrease in their populations. The croaker sex ratio, which is 50:50 among fish caught east of the Delta, is skewed toward males in the dead zone, and about one-fifth of the females in dead zone samples were found to have male germ cells in their ovaries. Laboratory experiments confirmed that only 10 weeks of exposure to hypoxia could induce these sexual defects. Depriving fish brains of oxygen apparently inhibits production of the neurohormones that promote normal ovary development. The croaker owes its name to its ability to make a drumming sound, but if the dead zone continues to expand and resulting sexual defects reduce their population growth rates, these fish might end up “croaking,” both literally and figuratively.

Human activities such as farming change the movement patterns of mineral nutrients, and these changes affect not just croakers but many organisms that live far from where the human activities take place.

How can we determine to what extent dead zones result from human actions and to what extent they are the result of natural processes?

See answer on p. 1225.

58.1 How Does Energy Flow through the Global Ecosystem?

An **ecosystem** includes all of the organisms in an ecological community as well as the physical and chemical factors that influence those organisms. In other words, ecosystems have both biotic and abiotic components. Ecosystems can occupy a wide range of spatial scales, from the entire planet to a watershed, a specific forest, a lake or pond, or even a patch of lichen on a rock. To some degree, ecologists must define the boundaries of ecosystems arbitrarily. In this chapter we will focus on the global ecosystem, noting that all smaller-scale ecosystems are linked by the global flows of energy and chemical elements that are considered in this chapter.

Energy flows and chemicals cycle through ecosystems

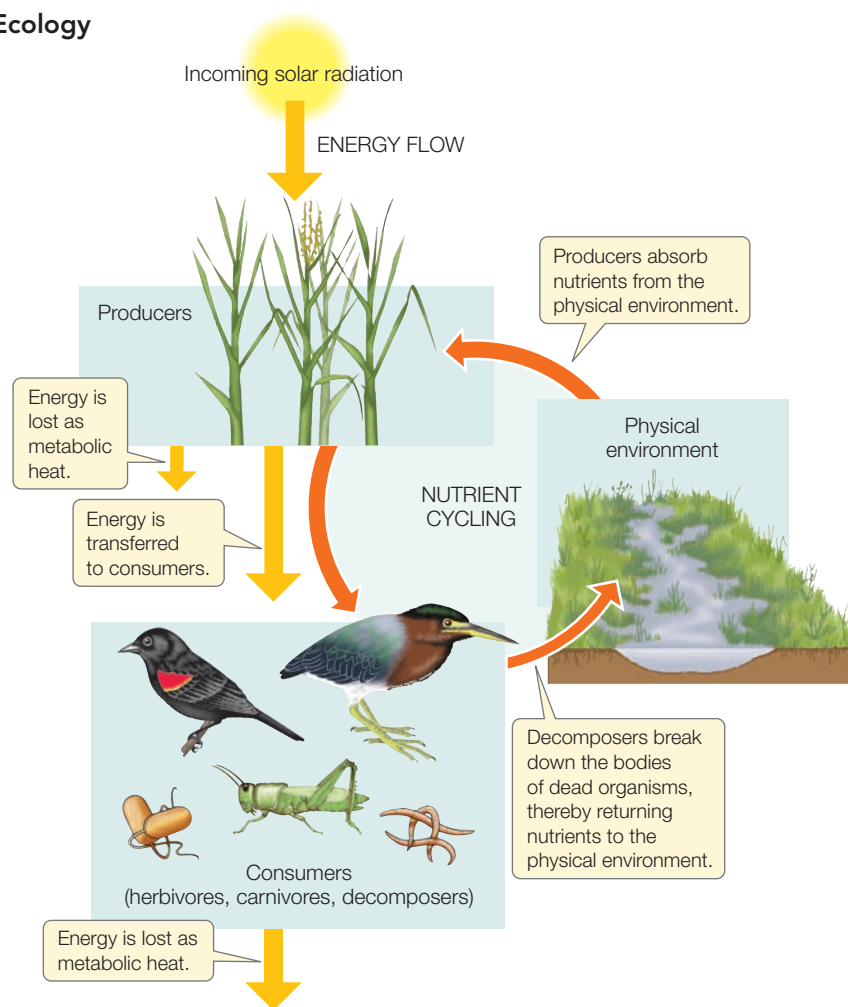

Earth is essentially a closed system with respect to chemical elements, but it is an open system with respect to energy. The sun delivers a nearly constant amount of energy to Earth every day and has done so for billions of years. When captured by primary producers such as plants and photosynthetic bacteria, that energy flows through the trophic levels of food webs in one direction (see Figure 57.3). Much of the energy that enters each trophic level is used to power the metabolism of producers and consumers; that energy is eventually dissipated as heat and is lost from the ecosystem (see Figure 57.2). Chemical elements, by contrast, are not altered when they are transferred between organisms. Furthermore, they are not lost from the global ecosystem, although they may become unavailable to organisms for long periods; instead chemical elements cycle continually between living organisms and the abiotic components of ecosystems (Figure 58.1).

In this first section we examine how the geographic distribution of incoming solar radiation influences the amount of energy assimilated by primary producers and how human activities are modifying energy flow through the global ecosystem.

The geographic distribution of energy flow is uneven

Nearly all energy used by organisms comes (or once came) from the sun. The only exceptions are found in those few ecosystems in which solar energy is not the main energy source (such as some caves and deep-sea hydrothermal vent ecosystems). Even the fossil fuels—coal, oil, and natural gas—on which the economy of modern human civilization is based are reserves of captured solar energy locked in the remains of organisms that lived (and died) millions of years ago (see Section 25.2).

As described in Section 57.1, solar energy enters ecosystems by way of plants and other photosynthetic organisms.

58.1 Energy Flows and Chemical Nutrients Cycle through Ecosystems Each time one organism eats another, a portion of the solar energy originally captured by a primary producer is lost as heat (gold arrows). As a result, energy flows through the ecosystem in a single direction. Chemical elements that organisms use as nutrients, however, cycle repeatedly between organisms and the physical environment (orange arrows).

These primary producers use some of the energy they assimilate for their own metabolism; the rest—net primary production (NPP)—is stored in their bodies or used for their growth and reproduction (see Figure 57.2). Because only the energy of NPP is potentially available to other organisms, which obtain it by consuming primary producers, NPP can be used as a rough measure of energy influx into an ecosystem. NPP varies among ecosystem types, but because ecosystem types also vary greatly in their geographic extent, the most productive ecosystem types do not necessarily contribute the most to Earth's net primary production (Figure 58.2).

The geographic distribution of NPP reflects the geographic variation in incoming solar radiation described in Section 54.2 and the climate patterns that result from it. In other words, the distribution of temperatures and moisture makes some ecosystems more productive than others (Figure 58.3). Close to the equator at sea level, temperatures are high throughout the year and the water supply is adequate for plant growth much of the time. In these climates, productive forests thrive. In deserts, plant growth is limited by lack of moisture and NPP is low. At higher latitudes, even though moisture is generally available, NPP is low because

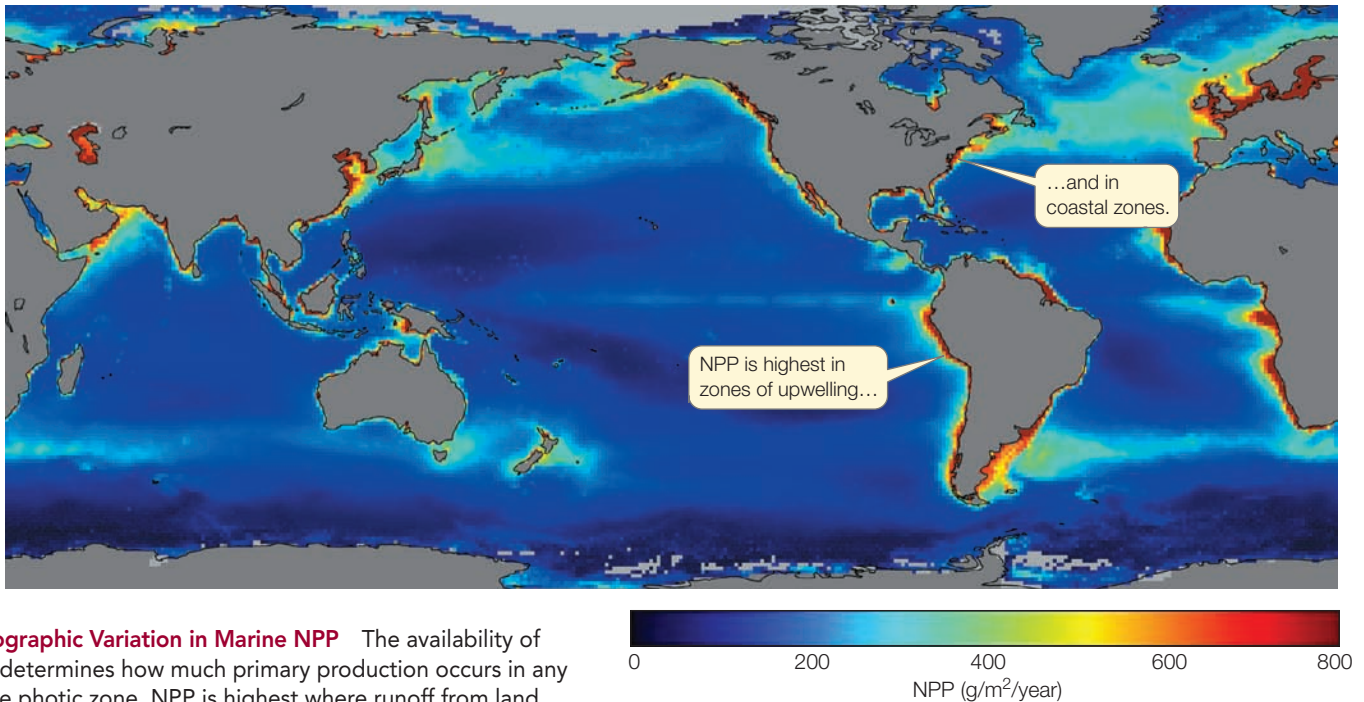

58.2 Energy Flow Contributions by Ecosystem Type The contributions of different ecosystem types to global energy flow can be measured by (A) their geographic extent and (B) their average net

primary productivity. (C) Combining these two measures gives us a proportional contribution of each ecosystem type to Earth's total net primary production.

58.3 Geographic Variation in Terrestrial NPP This map of estimated terrestrial net primary production is based on satellite sensor

data accumulated from 2000 through 2005. White spaces represent unvegetated areas, including deserts and ice caps.

58.4 Geographic Variation in Marine NPP The availability of nutrients determines how much primary production occurs in any part of the photic zone. NPP is highest where runoff from land brings nutrients into shallow coastal waters and where upwellings bring nutrients from the seafloor to the surface.

it is relatively cold much of the year and the growing season is short (see Working with Data, p. 1138).

Production in aquatic ecosystems is limited by light, which decreases rapidly with depth (see Figure 54.9), and by temperature, which also decreases with depth, except in areas on the seafloor near hydrothermal vents. Production in aquatic ecosystems is also strongly limited by nutrient availability, as we'll see in the following section. Net primary production in the oceans tends to be highest in coastal zones, where runoff from land and upwellings from deeper waters bring nutrients into shallow waters (**Figure 58.4**).

Human activities modify the flow of energy

The effects of human activities on energy flow through the global ecosystem have accelerated markedly in the last 150 years. Some human activities decrease net primary production, as when forests are cut down and replaced by cities; some increase it, as when prairies are converted to extensive agricultural fields.

Humans consume about one-quarter of Earth's average annual net primary production. More than 50 percent of this consumption results from the croplands and rangelands that occupy more than one-third of Earth's ice-free surface; another 40 percent results from productivity changes brought about by alterations in land use; and 7 percent represents biomass consumed in fires caused by humans. The percentage varies strikingly among regions, however; urban areas consume as much as 300 times the NPP they generate, but people in sparsely inhabited parts of the Amazon Basin consume vanishingly small amounts of the NPP generated there.

RECAP 58.1

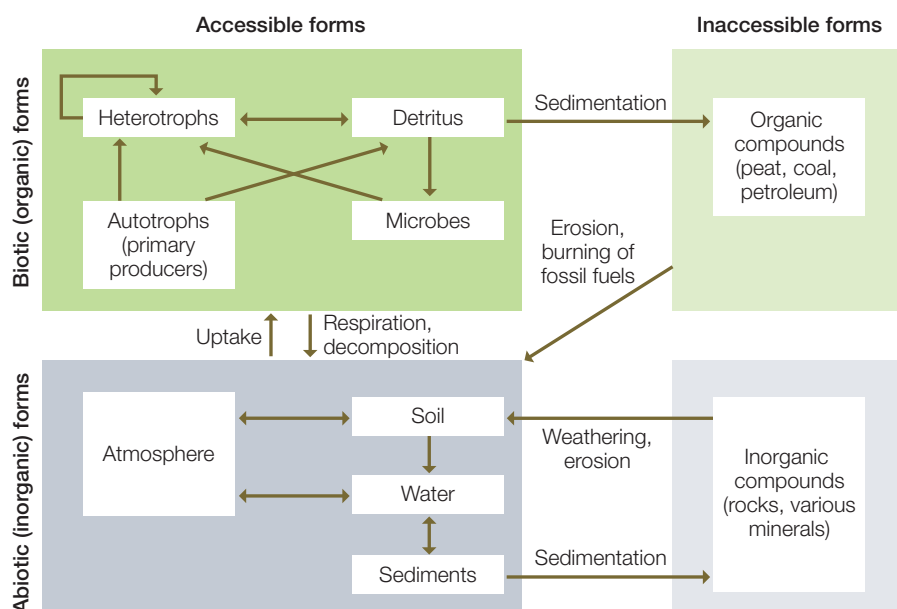

Nearly all energy used by living organisms comes from the sun. Energy flow through ecosystems, as measured by net primary production, varies with geographic location.

- How does the distribution of temperature and moisture influence the geographic distribution of net primary production in terrestrial systems? **See p. 1208 and Figure 58.3**
- What percentage of Earth's average annual net primary production is appropriated by humans, and how does that percentage vary regionally? **See p. 1210**

Ecosystem productivity is influenced not only by energy flow but also by the availability of the nutrients and other materials required by organisms to build their bodies and to power their metabolism. The next section will describe how biochemical materials and nutrients move around the abiotic environment and become available to living organisms.

58.2 How Do Materials Move through the Global Ecosystem?

In contrast to the energy that powers biological processes, which comes from the sun, the chemical elements that make up the bodies of organisms come from within the Earth system itself. As we have seen, these elements cycle continually through the global ecosystem. But they are not always available in the right place, or in the right form, to be useful to organisms. Because nutrient availability, in addition to energy input, influences productivity, ecologists are interested in knowing where on Earth nutrients are located and how they move from one location to another.

58.5 Chemical Elements Cycle through the Biosphere The different forms and locations of the chemical elements determine whether or not they are accessible to living organisms. Biological, geological, and chemical processes cycle matter among these biotic and abiotic components of the global ecosystem.

Energy from the sun, combined with energy from the radioactive decay in Earth's interior, drives the biological, geological, and chemical processes that transform chemical elements and move them around the planet (Figure 58.5). In this section we'll examine the properties of some of the abiotic and biotic components of the global ecosystem—referred to as compartments—through which elements move, as well as the processes that move them. The rate at which an element moves through a compartment is called its **flux**; the term “flux” is also applied to the movements of energy. Elements may accumulate, or “pool,” in some compartments.

Elements move between biotic and abiotic compartments of ecosystems

All materials in the bodies of organisms ultimately originate from abiotic sources, but organisms acquire these materials in many different ways. Autotrophs such as plants take up certain elements directly from soil, water, and the atmosphere and incorporate them into organic molecules to build biomass. Heterotrophs generally acquire elements by consuming the biomass produced by other organisms, then reassemble those elements, via chemical reactions, in different ways. Some heterotrophs, however, acquire some elements by housing mutualistic microbes that convert those elements into forms that are usable by their hosts.

Respiration by living organisms returns certain elements to the atmosphere as gases. After organisms die, the materials in their bodies become detritus and are broken down by decomposers into simpler biochemical components. In this way the elements are freed to be taken up again by autotrophs. Elements that do not get taken up by autotrophs can accumulate in soil, water, or sediments.

At times in the remote past, great quantities of organic material were removed from active cycling when organisms died in large numbers and were buried in sediments that lacked oxygen. In such anaerobic environments, decomposers could not efficiently break down organic molecules to their inorganic forms. Instead organic molecules accumulated and were eventually transformed into deposits of oil, natural gas, coal, or peat—the **fossil fuels** that modern humans use as a combustible source of energy.

The movement of elements through food webs from uptake to decomposition—that is, through the biotic compartments of ecosystems—occurs primarily on a local scale. In contrast, abiotic processes can move elements far beyond the boundaries of the local ecosystem. The various abiotic compartments of the global ecosystem differ in fundamental ways, and the quantities of different elements in each compartment (e.g., atmosphere, ocean, soil), how long those elements remain there (their **residence time**), the forms they take, and the rates at which they enter and leave also differ. Moreover, the cycling of nutrients among compartments is influenced by the ways in which energy flows through them.

The atmosphere contains large pools of the gases required by living organisms

The outermost compartment of the global ecosystem is the atmosphere, a thin layer of gases surrounding Earth. The atmosphere is 78.08 percent nitrogen gas (N_2), 20.95 percent oxygen gas (O_2), 1 percent water vapor, 0.93 percent argon, and 0.03 percent carbon dioxide (CO_2). It also contains traces of hydrogen gas, neon, helium, krypton, xenon, ozone, and methane. It contains Earth's biggest pool of nitrogen as well as a large proportion of its oxygen.

About 80 percent of the mass of the atmosphere lies in its lowest layer, the **troposphere**. This layer extends upward from Earth's surface about 17 km in the tropics and subtropics, but only about 10 km at high latitudes. Most global air circulation takes place within the troposphere, and virtually all of the atmospheric water vapor is found there (Figure 58.6).

The **stratosphere**, which extends from the top of the troposphere up to about 50 km above Earth's surface, contains very little water vapor. Most materials enter the stratosphere from the region of the troposphere that encircles the equator, where air heated by the sun's energy rises to high altitudes (see Section 54.2).

The stratosphere contains a layer of ozone (O_3) that absorbs most of the biologically damaging ultraviolet radiation that enters the atmosphere. Over the last several decades, this **ozone layer** has been seriously damaged by human activities, particularly the widespread release of chlorinated fluorocarbons (CFCs), such as the refrigerant freon. CFCs remain stable as they ascend to the stratosphere, where they interact with and break

58.6 Earth's Atmosphere Has Two Layers

The troposphere and the stratosphere differ in their circulation patterns, the amount of water vapor they contain, and the amount of ultraviolet radiation they receive.

down ozone molecules in the presence of ultraviolet light. The more ozone that is lost, the more ultraviolet light can reach Earth's surface. Increases in ultraviolet radiation are associated with increased rates of skin cancer, cataract formation, and crop damage. Since 1989, when a global treaty was enacted to phase out production of CFCs, atmospheric levels of CFCs have for the most part stabilized or declined, and there is encouraging evidence from both satellite and ground station measurements that stratospheric ozone levels are slowly returning to their normal state.

The atmosphere moderates temperatures at and near Earth's surface by trapping heat energy. If Earth had no atmosphere, its average surface temperature would be about -18°C , rather than its actual $+17^{\circ}\text{C}$. Carbon dioxide, methane (CH_4), nitrous oxide (N_2O), water vapor, and certain other gases in the atmosphere are known as **greenhouse gases** because they are transparent to sunlight but trap heat radiating from Earth's surface back toward space (Figure 58.7). Ozone, when it is present in the troposphere rather than the stratosphere, also

acts as a greenhouse gas. As we'll see later in this chapter, human activities are increasing the concentrations of greenhouse gases in the atmosphere, and those increases are altering the climate.

58.7 Radiant Energy Warms the Planet Solar energy input (yellow arrows) is absorbed by Earth's atmosphere and surface. Much of this energy is radiated from Earth's surface in the form of heat (orange arrows). Much of this radiation is prevented from escaping back into space by greenhouse gases in the atmosphere. The

widths of the arrows here are roughly proportional to the sizes of the energy fluxes.

Earth's Radiation Balance
Life10e.com/at58.1

The terrestrial surface is influenced by slow geological processes

About one-fourth of Earth's surface consists of land above sea level. Because the geological processes that move elements through minerals and soils are so slow, regional and local variations in the supply of particular elements greatly influence terrestrial ecosystem processes.

Nearly all the rocks that underlie the continents have been transformed at least once through a complex cycle of plate tectonic processes (see Figure 25.3). The physical and chemical processes of weathering break down surface rocks into soil. The type of soil in an area and the chemical nutrients that soil contains are determined in large part by the underlying rock from which the soil forms, although climate, topography, the local biota, and the length of time that soil-forming processes have been acting also influence the nature of soil (see Section 36.3). Chemical elements in rocks are released by weathering and by certain biological processes; these elements are then carried in solution into streams and groundwater, which transport them ultimately into the oceans. Structural features of the land surface affect how rapidly and in what direction wind and water currents can transport elements.

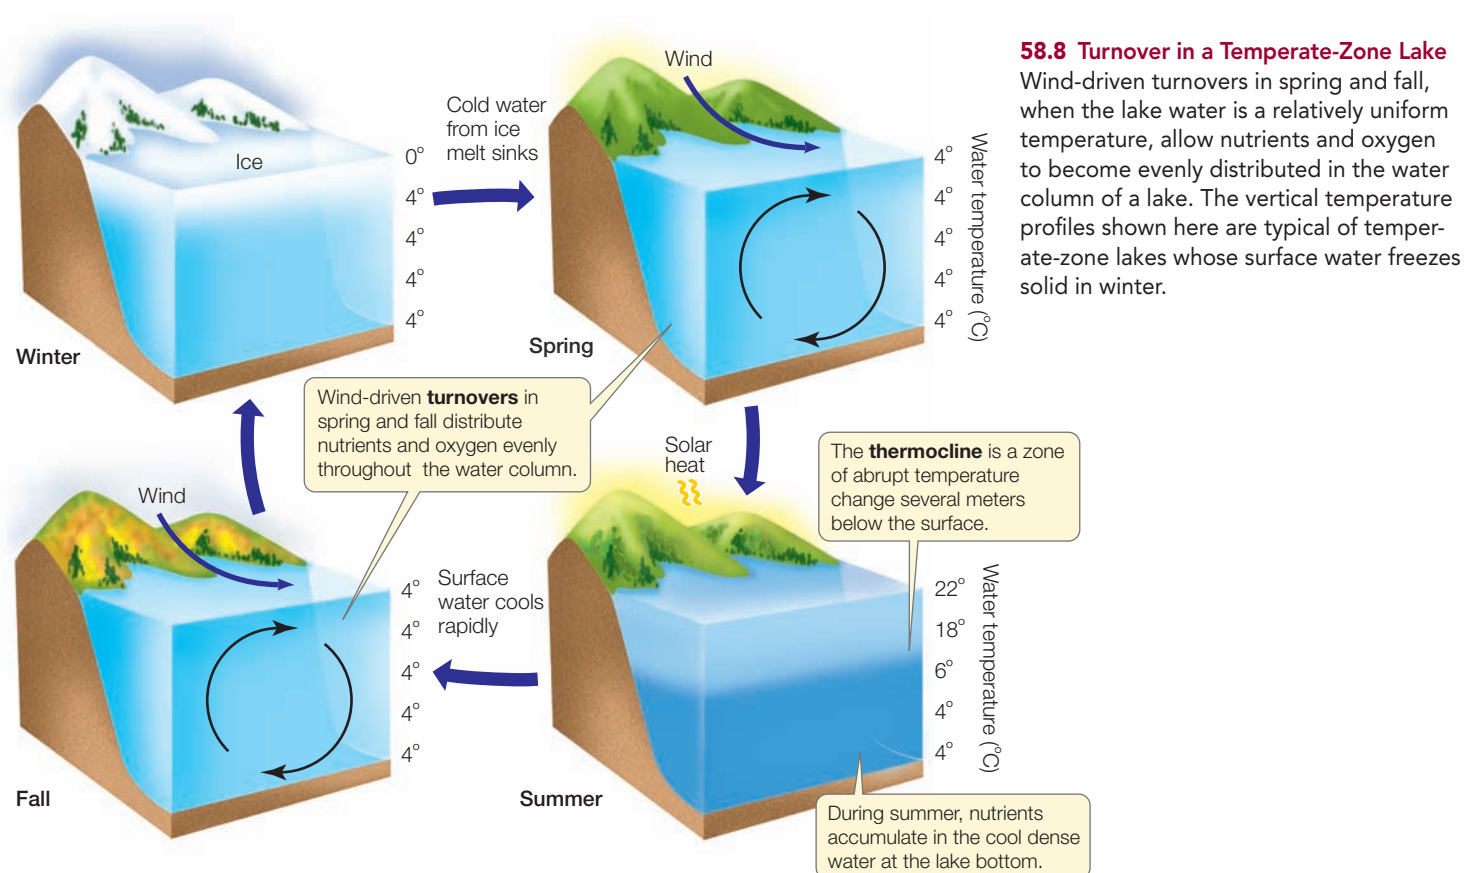

Water transports elements among compartments

The high heat capacity of water and its ability to change states from gas to liquid to solid at temperatures found on Earth (see Section 2.4) mean that it can move freely among all

compartments, including the biosphere. Water is a powerful solvent that can carry materials in solution within and among all the compartments of the global ecosystem.

FRESH WATERS The liquid fresh waters of the global ecosystem consist of streams, lakes, and **groundwater** (water occupying pore spaces in rock, sand, and soil). Only a small fraction of Earth's water resides in lakes and streams at any given time, but because water moves so rapidly through the freshwater compartment, most of Earth's water spends some time there. Some mineral nutrients enter fresh waters from the atmosphere in rainfall, but most are released from rocks by weathering. They are dissolved and carried into streams by surface runoff or by movements of groundwater in a process called erosion. After entering streams, mineral nutrients are usually carried rapidly to lakes or to the oceans.

TURNOVER IN LAKES The nutrients in lakes are taken up by and incorporated into the bodies of the organisms living there. Those organisms eventually die and sink to the lake bottom, where decomposition of their tissues by microbes releases the nutrients but consumes most of the oxygen in the bottom water. The surface waters of deep lakes thus quickly become depleted of nutrients while deeper waters become depleted of oxygen. The waters of most deep lakes in temperate climates have an annual cycle of **turnover**, vertical movements of the water column that bring nutrients to the surface and oxygen to deeper water (Figure 58.8).

58.8 Turnover in a Temperate-Zone Lake

Wind-driven turnovers in spring and fall, when the lake water is a relatively uniform temperature, allow nutrients and oxygen to become evenly distributed in the water column of a lake. The vertical temperature profiles shown here are typical of temperate-zone lakes whose surface water freezes solid in winter.

Turnover depends on the unique physical properties of water. Liquid water is densest at 4°C, a few degrees above its freezing point of 0°C (at which point it becomes solid and floats). Above 4°C, water expands. Thus in winter the coldest liquid water in a lake is at the surface, often just beneath a layer of ice, and the dense waters of the depth remain at 4°C. In spring, when the sun melts the ice and warms the surface water to 4°C, there is a time at which water density is uniform throughout the lake, and even modest winds will readily mix the entire water column. As spring and summer progress, the surface water becomes warmer still, and the depth of the warm water layer gradually increases. However, there is a well-defined depth, called the **thermocline**, at which the temperature changes abruptly. Only if the lake is shallow enough so that water warms up all the way to the bottom does the temperature of the deepest water rise above 4°C.

Another turnover occurs in fall as the process reverses itself. The surface of the lake cools until the water there is denser than the warmer water below it, at which point it sinks and is replaced by warmer water from below. Once again, water density becomes uniform, and winds can mix the entire water column.

A similar process contributes to the formation of the Gulf of Mexico dead zone described at the opening of this chapter, but in that case the density differences are caused by differences in salinity rather than in temperature. Fresh water is less dense than salt water, so when the nutrient-rich fresh water of the Mississippi River flows into the Gulf, it does not mix with the salt water but floats on top of it. Dying algae sink to the bottom, and bacterial decomposition depletes the available oxygen there. The difference in water density prevents oxygen from the surface water from mixing with the hypoxic salt water below.

OCEANS Over time scales of hundreds to thousands of years, most materials that cycle through the global ecosystem end up in the oceans, which hold almost 97 percent of Earth's water. The oceans are enormous, but they exchange materials with the atmosphere only at their surfaces, so they respond very slowly to inputs from that compartment. They receive materials from land primarily in runoff from rivers.

Except on continental shelves—the shallow ocean waters surrounding large land masses—ocean waters mix slowly. Most materials that enter the oceans from the land or the atmosphere gradually sink to the seafloor, where they may remain for millions of years, until intermittent plate tectonic processes lift seafloor sediments above sea level. Thus concentrations of mineral nutrients in most ocean waters are very low (except where human activities have released materials into the water).

Near the coasts of continents, however, offshore winds may push the warmer surface waters away from shore, causing cold water from the bottom to rise and bringing nutrients back to the surface waters. An area where water from depths below 50 meters rises in this way is known as an **upwelling zone**.

Upwelling zones support high rates of primary production by phytoplankton, which in turn support dense consumer populations. Most of the world's great fisheries are concentrated in upwelling zones. For example, the upwelling zone off the coast of Peru is the source of much of the world's supply of anchovies. This rich fish population supports vast seabird communities, which in turn produce enormous quantities of guano, or excrement, that have provided Peru with an important raw material to support a major fertilizer industry.

Fire is a major mover of elements

Every year 200 to 400 million hectares of savannas, 5 to 15 million hectares of boreal forests, and smaller expanses of other biomes catch fire and burn. Lightning ignites some of these fires, but humans start most of them to manage vegetation (as when they cut down and burn forests to clear land for growing crops). Fires rapidly consume the energy stored in, and release the chemical elements from, the vegetation they burn. Some nutrients, such as nitrogen, are readily vaporized by fire. Nitrogen enters the atmosphere in smoke or is carried into groundwater by rain falling on burned ground.

Fires also release large amounts of carbon into the atmosphere. The global annual flux of carbon to the atmosphere from savanna and forest fires is estimated at 1.7 to 4.1 petagrams (1 pg = 10^{15} g or 10^{12} kg). Biomass burning (which includes combustion of wood and alcohol, wildfires, and land clearing, but not the burning of fossil fuels) is responsible for about 40 percent of Earth's annual flux of CO₂ into the atmosphere and contributes to the production of other greenhouse gases as well. Large-scale wildfires in the western and southeastern United States can release as much CO₂ into the atmosphere as motor vehicles in those regions release over an entire year.

RECAP 58.2

Biological, geological, and chemical processes move materials within and among biotic and abiotic compartments of the global ecosystem.

- How does the atmosphere keep temperatures at and close to Earth's surface warmer than they would be in its absence? See pp. 1211–1212 and Figure 58.7
- Describe the process of turnover in a temperate-zone lake in fall. See pp. 1213–1214 and Figure 58.8

As we learned in Chapters 3 and 10, most of the chemical energy that primary producers convert from sunlight is stored in carbon-containing compounds. In the next section we will consider how carbon and other chemical elements required by living organisms cycle through the biotic and abiotic compartments of the global ecosystem.

58.3

How Do Specific Nutrients Cycle through the Global Ecosystem?

Each of the chemical elements that organisms use in large quantities cycles in a distinctive way through the biotic and

58.9 The Global Hydrologic Cycle

As described in Section 2.4, the unique properties of water are essential to life as we know it on Earth. The numbers in parentheses show the estimated amounts of water (expressed as exagrams, one exagram equalling 10^{18} g or 10^{15} kg) held in or exchanged annually by fluxes (arrows) among compartments of the global ecosystem. The widths of the arrows are proportional to the sizes of the fluxes.

The Global Hydrologic Cycle
Life10e.com/at58.2

abiotic compartments of the global ecosystem. Because geological, chemical, and biological processes are all important in moving materials around the planet, the pattern of movement of an element is called its **biogeochemical cycle**. The nature of each biogeochemical cycle depends on the physical and chemical properties of the element and on the ways in which it is used by organisms.

Water cycles rapidly through the ecosystem

In addition to being a compartment of the global ecosystem where nutrients are found and a medium that transports those nutrients between other compartments, water is itself a material. Water cycles through the ecosystem in the global **hydrologic cycle** (Figure 58.9).

Energy from the sun drives the hydrologic cycle, taking up water by evaporation from the vast surfaces of the oceans. The cycle operates because more water evaporates from the ocean surfaces than is returned to the oceans in the form of precipitation. On land, water evaporates from soils, lakes, and rivers and is taken up from the leaves of plants by transpiration. However, the total amount evaporated and transpired from terrestrial surfaces is less than the amount that falls on them as precipitation. Excess terrestrial precipitation eventually returns to the oceans via streams, coastal runoff, and groundwater flows. More than half of this volume of water is carried back to the oceans by Earth's four largest rivers: the Amazon in South America, the Nile in Africa, the Mississippi in North America, and the Yangtze in Asia.

Despite their relatively small volume, rivers play a disproportionate role in the hydrologic cycle because the average residence time of a water molecule in rivers is only a few years. By comparison, the average residence time of a water molecule in lakes ranges from a few years to centuries. The larger the lake,

the longer the residence time; the residence time for water in the top portion of Lake Superior, for example, is 1,500 to 2,000 years, and the water at the bottom of this massive lake never cycles. In the oceans the average residence time of a water molecule is about 3,000 years. Other pools of water include glaciers (with residence times of 20–100 years), seasonal snow cover (a few months), and soil moisture (1–2 months). The average residence time of water in the bodies of organisms is particularly brief, averaging just under a week.

Although large amounts of groundwater are present in underground pools called **aquifers**, this water has a long residence time underground and plays only a small role in the hydrologic cycle. In some places, however, aquifers are being depleted because humans are using groundwater more rapidly than it can be replaced, primarily by pumping it for irrigation. Much of the groundwater being used today in the Northern Hemisphere was deposited during the most recent ice age, when regional precipitation was much greater than it is now. Using this groundwater for irrigation and other purposes has increased flows of water to the oceans and has contributed to the sea level rise of the past century.

The effects of groundwater depletion are already being felt. On the North China Plain, depletion of shallow aquifers is forcing people to sink wells more than 1,000 meters deep to reach groundwater. Worldwide, more than 1 billion people have no access to safe drinking water. If current water consumption patterns continue, by 2025 at least 48 percent of the current world population will live in areas with inadequate water supplies. However, per capita water consumption in the United States and Europe is declining as a result of increasing use of water-efficient home appliances as well as implementation of new regulations that restrict water use. If such trends continue, global water use in 2025 could be lower than it is today, despite continued population growth.

58.10 The Global Carbon Cycle Carbon is the basis of the organic molecules essential to life. The numbers in parentheses show the quantities of carbon in petagrams (1 pg = 10^{15} g or 10^{12} kg) held in or exchanged annually by fluxes (arrows) among compartments of the global ecosystem. The widths of the arrows are proportional to the sizes of the fluxes.

The Global Carbon Cycle
Life10e.com/at58.3

The carbon cycle has been altered by human activities

As described in Part One of this book, all of the important macromolecules that make up living organisms contain carbon, and much of the energy that organisms use to fuel their metabolic activities is stored in carbon-containing (organic) compounds. Carbon in the atmosphere, in the form of CO₂, is taken up by autotrophs and incorporated into organic molecules by photosynthesis. All heterotrophic organisms obtain carbon by consuming autotrophs or other heterotrophs, their remains, or their waste products.

On land, biological processes move carbon directly between organisms and the atmosphere as terrestrial organisms take up carbon during photosynthesis and return it to the atmosphere through respiration and metabolism. In contrast, carbon dioxide moves into ocean waters from the atmosphere primarily by simple diffusion at the ocean surface; this dissolved CO₂ is the source of the carbon used by marine primary producers (Figure 58.10). Even taken together, however, the amounts of carbon in the atmosphere, in soils, and in living and dead organisms are dwarfed by the vast quantities of carbon stored in terrestrial rocks, in fossil fuels, in marine sediments, and in seawater in the form of carbonate ions (CO₃²⁻) or bicarbonate ions (HCO₃⁻).

At times in the remote past, quantities of carbon were removed from active cycling when organisms died in large numbers and were buried in sediments lacking oxygen. In such anaerobic environments, with no detritivores to reduce organic carbon to CO₂, organic molecules accumulate and are eventually transformed into deposits of oil, natural gas, coal, or peat. Humans have discovered and used these fossil fuels at ever-increasing rates during the past 150 years. As a result, CO₂, one of the final products of burning fossil fuels, is being released into today's atmosphere faster than it is dissolving in the oceans or being incorporated into terrestrial biomass (Figure 58.11). Based on a variety of calculations, atmospheric scientists estimate that

before the Industrial Revolution, the concentration of CO₂ in Earth's atmosphere was probably about 265 parts per million. Today it is 392 parts per million, representing a rate of increase more than 10 times faster than at any other time for millions of years.

WHERE HAS ALL THE CARBON GONE? Less than half of the CO₂ released into the atmosphere by human activities remains in

58.11 Atmospheric CO₂ Concentrations Are Increasing Carbon dioxide concentrations, expressed as parts per million by volume of dry air, have been recorded since 1960 on top of Mauna Loa, Hawaii, far from most sources of human-generated CO₂ emissions. Although concentrations vary seasonally, the trend has been consistently upward.

the atmosphere. Where does the rest of the CO_2 wind up? Much of it is dissolved in the oceans in inorganic forms. Over decades to centuries, the oceans, which contain 50 times more carbon than the atmosphere, determine atmospheric CO_2 concentrations. The rate at which CO_2 diffuses from the atmosphere into the oceans depends in part on photosynthesis by phytoplankton in the surface waters. These organisms remove dissolved CO_2 from water, thereby increasing the rate at which atmospheric CO_2 is absorbed by surface waters. In addition, many marine organisms (including clams, oysters, corals, and planktonic foraminiferans) incorporate carbon in their shells and other structures in the form of calcium carbonate (CaCO_3), which is synthesized by combining bicarbonate ions (HCO_3^-) and calcium ions (Ca^{2+}) dissolved in seawater. When these organisms die, those shells and their embedded carbon sink to the ocean floor.

Today's oceans absorb 20 to 25 million tons of CO_2 from the atmosphere each day—more than at any time during the past 20 million years. As a result, water near the ocean surface is becoming more acidic. As CO_2 concentrations in the atmosphere rise, more of the gas diffuses into the water at the ocean surface, where it reacts with water to form carbonic acid (H_2CO_3). As levels of carbonic acid rise, the pH of seawater drops. This increase in acidity can have negative effects on many marine organisms, particularly corals. The combination of decreasing pH and increasing water temperature to which corals are being exposed kills their symbiotic algae, “bleaching” the corals and killing them as well (see Figure 27.21). Because so many other reef species depend on corals and the structure they provide, the entire reef community can collapse if the corals fail to thrive.

Photosynthesis by terrestrial vegetation, principally in forests and savannas, typically absorbs about the same amount of carbon that is released by terrestrial metabolism—about half of it released by plants and half by microbes in the soil that break down plant detritus. The photosynthetic consumption of CO_2 currently exceeds the metabolic production of CO_2 , which means Earth's terrestrial vegetation is storing carbon that would otherwise be increasing atmospheric CO_2 concentrations—but we cannot count on terrestrial vegetation to store the vast amounts of excess CO_2 that human activities produce. Furthermore, climate warming (another result of increasing atmospheric CO_2 concentrations, as we will see next) increases plant metabolism and is thus likely to increase the flux of CO_2 from vegetation into the atmosphere.

ATMOSPHERIC CO_2 AND GLOBAL CLIMATE CHANGE Carbon dioxide is a greenhouse gas, so we would expect increasing atmospheric CO_2 concentrations to raise temperatures at Earth's surface. What evidence do we have that this is occurring? Measurements of gases in air trapped in the Antarctic and Greenland

58.12 Higher Atmospheric CO_2 Concentrations Correlate with Warmer Temperatures

Atmospheric concentrations of CO_2 (measured in air bubbles trapped in Antarctic ice) have varied with temperatures over Antarctica (estimated by a technique known as oxygen isotope analysis).

ice caps show that atmospheric CO_2 concentrations have been higher when Earth has been warmer and lower when it has been cooler (Figure 58.12). For example, the atmospheric CO_2 concentration was very low during the most recent glaciation, between 30,000 and 15,000 years ago, when temperatures were presumably much colder than they are today. In contrast, during a warm interval 5,000 years ago, atmospheric CO_2 concentration may have been slightly higher than it is today.

How global climates and ecosystems will change in response to this rapid warming is a subject of intense investigation. Complex computer models of the global ecosystem indicate that a doubling of today's atmospheric CO_2 concentration would increase mean annual temperatures worldwide and would probably result in droughts in the central regions of continents, but would increase precipitation in coastal areas. Global warming has already resulted in the shrinking of Arctic sea ice (Figure 58.13). The five smallest expanses of Arctic sea ice ever measured were recorded in the past six years; overall Arctic sea ice extent is declining by 3.5 to 12 percent per decade. Based on scientific climate models, if glacial ice continues to melt and temperatures continue to rise, sea level will rise (because of both thermal expansion of ocean waters and the addition of glacial meltwater), increasing the probability of flooding of coastal cities and agricultural lands.

Global climate warming is having profound effects on the distributions and abundances of species and, consequently, on species interactions. One clear example is an increase in the severity of insect infestations in certain temperate forest communities. Pine trees in some temperate forests are attacked by pine bark beetles, which carry with them a symbiotic fungus that infects the trees and helps the beetles overcome the trees' defenses (see Figure 56.9). In Colorado, cold winters have

58.13 Shrinking Ice Caps A NASA satellite image shows the extent of Arctic sea ice (bright white) on September 16, 2012. The plus symbol marks the geographic North Pole. The extent of the ice cap in 2012 was about one-half that of the September 16 mean for the years 1979–2000.

historically limited the ability of these beetles to kill many trees. In 2008, however, Colorado experienced an outbreak of mountain pine beetles that destroyed more than 400,000 hectares (1 million acres) of trees. The lack of an extended period of below-zero temperatures in the previous winter had allowed large numbers of overwintering beetles to survive.

The nitrogen cycle depends on both biotic and abiotic processes

Nitrogen gas is the most abundant gas in Earth's atmosphere, but most organisms cannot use nitrogen in its gaseous form.

Only a few species of microorganisms can convert atmospheric N_2 into forms such as ammonia and nitrate that are usable by plants, a process called nitrogen fixation (see Figure 36.10). Other microorganisms carry out denitrification, the principal process that removes nitrogen from the biosphere and returns it to the atmosphere as N_2 . Collectively this microbial processing of nitrogen accounts for about 95 percent of all natural nitrogen flux on Earth (**Figure 58.14**).

Abiotic weathering is an important source of nitrogen in some terrestrial ecosystems. In temperate forests growing on land underlain by nitrogen-rich sedimentary rocks, for example, the soils and foliage have 50 percent higher levels of nitrogen than in temperate forests growing on land underlain by nitrogen-poor igneous rocks.

All living organisms require nitrogen, and the inability of the vast majority of organisms to use N_2 means that usable nitrogen is often in short supply. Populations of nitrogen-fixing organisms

rarely increase in abundance to the extent that nitrogen is no longer limiting because the end products of their nitrogen fixation are rapidly lost from ecosystems (ammonia by vaporization and denitrification; and nitrate, which is highly water-soluble, by leaching).

Human activities that fix nitrogen, such as the manufacture of artificial fertilizers, have had some unanticipated effects on the nitrogen cycle. The extensive use of artificial fertilizers on agricultural crops, coupled with the burning of fossil fuels (which generates nitric oxide and nitrogen dioxide), has resulted in total nitrogen fixation by humans being nearly equal

58.14 The Global Nitrogen Cycle The largest pool of nitrogen is held in the atmosphere in the form of nitrogen gas, N_2 . Nitrogen cycles through the biosphere primarily via the processes of nitrogen fixation, which converts inorganic nitrogen to an organic form usable by plants, and denitrification, which returns N_2 to the atmosphere. The numbers in parentheses show the quantities of nitrogen in teragrams ($1 \text{ tg} = 10^{12} \text{ g}$ or 10^9 kg) exchanged annually by compartments of the global ecosystem. The widths of the arrows are proportional to the sizes of the fluxes.

The Global Nitrogen Cycle
Life10e.com/at58.4

58.15 Human Activities Have Increased Nitrogen Fixation Most of the nitrogen fixed by industrial processes is used in agricultural fertilizers. Some fixation is a by-product of fossil fuel combustion. Fixation by natural processes in managed agroecosystems (e.g., by legumes grown as crops) also contributes to anthropogenic (human-caused) effects on nitrogen flux.

to global natural nitrogen fixation (Figure 58.15). This human-generated nitrogen flux has been increasing over the past half-century and is expected to continue to increase.

Eutrophication is an increase in biomass production in a body of water due to inputs of nutrients. Eutrophication occurs naturally as part of the aging process in lakes. As lakes become more shallow with the accumulation of sediments brought in by streams, their water warms more rapidly with the onset of summer, and exploding populations of photosynthetic cyanobacteria and single-celled algae, called blooms, can deplete oxygen levels (see Figure 26.9C). Human nutrient inputs greatly increase the likelihood and frequency of these blooms. When more nitrogen fertilizer is applied to croplands than can be taken up by the crops, the excess nitrogen moves out of the system in surface runoff, or downward into groundwater, and ultimately ends up in rivers, lakes, and oceans. The dead zone that has formed near the mouth of the Mississippi River in the Gulf of Mexico, described at the opening of this chapter, is a result of water flows from agricultural fields in the U.S. interior carrying high concentrations of nitrogen from fertilizer.

The human increase in nitrogen fixation has also increased atmospheric concentrations of the greenhouse gas nitrous oxide (N_2O), resulting in the production of tropospheric ozone—also a greenhouse gas—and smog. Some of the nitrogen that enters the atmosphere falls back to land in precipitation or as dry particles. This deposition of nitrogen from the atmosphere has increased dramatically during recent decades. Nitrogen deposition affects the composition of terrestrial vegetation by favoring those plant species that are best adapted to take advantage of high nutrient levels, which then outcompete other species. Spatial variation in nitrogen deposition rates has

allowed ecologists to determine that plant species richness in grasslands declines as the rate of nitrogen deposition increases. Rates of nitrogen deposition are high enough over much of Europe and eastern North America to cause substantial reductions in species richness in grasslands on both continents.

The burning of fossil fuels affects the sulfur cycle

As a component of proteins, sulfur is required by all organisms. Most of Earth's sulfur supply is locked up in rocks on land and as sulfate salts in deep-sea sediments, but some sulfur moves between the atmosphere and land. Emissions of the gases sulfur dioxide (SO_2) and hydrogen sulfide (H_2S) from volcanoes account for between 10 and 20 percent of the total natural abiotic flux of sulfur to the atmosphere, but they occur only intermittently (although volcanic eruptions spew great quantities of sulfur over broad areas, they are rare events). In the atmosphere, H_2S can combine with oxygen to form SO_2 , which dissolves in atmospheric water and reaches the ground as sulfuric acid in precipitation and fog.

When sulfur in the soil comes in contact with atmospheric oxygen, it is converted to sulfate salts, which can be taken up by plants and incorporated into proteins. This sulfur ultimately is returned to the atmosphere via microbial decomposition. In marine systems, too, microbial decomposition is important in returning sulfur to the atmosphere. Many marine phytoplankton and seaweeds manufacture large quantities of a sulfur-containing compound (dimethylsulfoniopropionate, or DMSP) to maintain their salt and water balance. When broken down, DMSP releases dimethyl sulfide (CH_3SCH_3), the principal odorant of rotting seaweed stench. Because the quantities of phytoplankton in the oceans are enormous, dimethyl sulfide production accounts for about half of the biotic component of the global sulfur cycle.

Atmospheric sulfur plays an important role in global climate. Even if air is moist, clouds do not form readily unless there are small particles in the atmosphere around which water can condense. Dimethyl sulfide is the major component of such particles, so increases in atmospheric sulfur concentrations increase cloud cover and reduce the amount of incoming solar radiation that ultimately reaches Earth's surface.

Human use of fossil fuels alters the sulfur cycle as well as the carbon and nitrogen cycles. The combustion of fossil fuels releases sulfur in the form of SO_2 , as well as nitrogen in the form of nitrogen dioxide (NO_2), into the atmosphere. Both compounds react with water molecules in the atmosphere to form sulfuric acid (H_2SO_4) and nitric acid (HNO_3), respectively. These acids can travel hundreds of kilometers in the atmosphere before they settle to Earth as dry particles or in precipitation. Rain or snow that contains enough nitric and sulfuric acid to lower its pH is called **acid precipitation**.

Acid precipitation now falls in all major industrialized countries and is particularly widespread in eastern North America and Europe. The normal pH of unpolluted precipitation is about 5.6, but precipitation in New England now averages about pH 4.5, and there have been occasional rainfalls

58.16 Acidification Reduces Fish Species Richness The average number of fish species found in lakes sampled in the Adirondack region of New York is directly correlated with pH. Numbers in the bars indicate the number of lakes in each pH range.

and snowfalls with a pH as low as 3.0. Precipitation with a pH of about 3.5 or lower damages the leaves of plants and reduces rates of photosynthesis. Acidification of lakes in the Adirondack region of New York State has reduced fish species richness by causing the extinction of acid-sensitive species (Figure 58.16). Many invertebrates that are primary consumers in aquatic communities are sensitive to pH; in particular, multiple species of mayflies and caddisflies (important food resources for fish) have experienced local population reductions in acidified streams around the world. Even when its effects are not lethal, acidification can have subtle effects on behavior that reduce the viability of aquatic organisms. Diving beetles, for example, lose their ability to regulate their underwater oxygen supply when pH levels drop significantly.

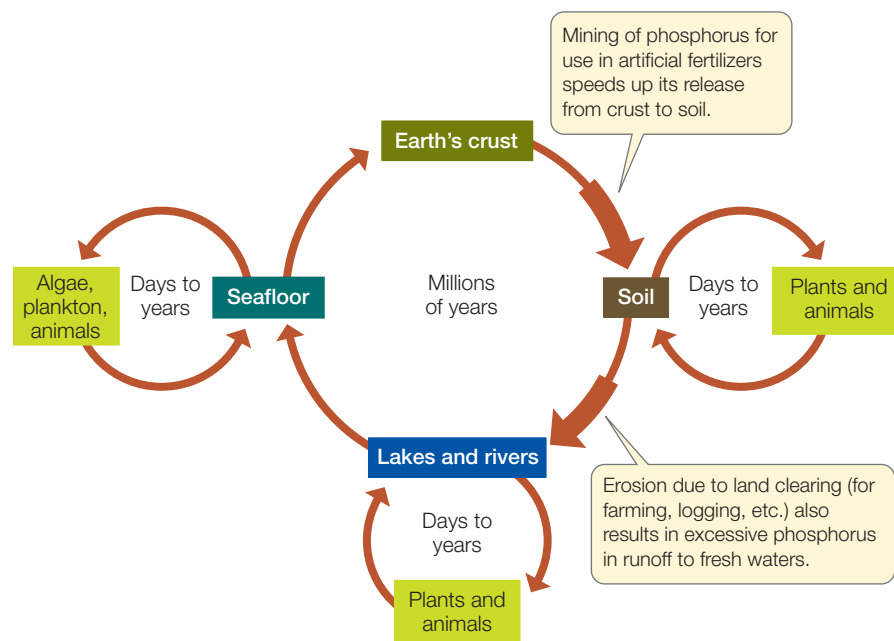

Regulations instituted by the U.S. Clean Air Act in 1990 have raised the pH of precipitation in much of the eastern United States, primarily by lowering sulfur emissions. There are indications that once emissions have been reduced, acidified aquatic systems can recover quickly. David Schindler at the University of Alberta studied the effects of acid precipitation by adding enough H_2SO_4 to two small Canadian lakes to reduce their pH from about 6.6 to a moderately acidic level of 5.2. In both lakes, nitrifying bacteria failed to survive, and nitrogen cycling within the lake was blocked. When Schindler stopped adding acid to one of the lakes, its pH returned to its original value in about a year and nitrification resumed. That said, the larger organisms

in acidified aquatic systems may be slower to bounce back. In Wales, investigators conducted a 25-year study of 14 rivers to determine the impacts of acid rain reduction. They were disappointed to find that, even after that length of time, only 4 insect species—2 mayfly species and 2 caddisfly species—had recolonized the rivers out of the 29 species that should have been able to live under the ameliorated conditions.

The global phosphorus cycle lacks a significant atmospheric component

Phosphorus accounts for only about 0.1 percent of Earth's crust, but it is an essential nutrient for all life forms. It is a key component of DNA, RNA, and ATP. Unlike the other biogeochemical cycles discussed thus far, the phosphorus cycle lacks a significant gaseous component (Figure 58.17). Some phosphorus is transported on dust particles, but very little of the phosphorus cycle takes place in the atmosphere. Most of Earth's phosphorus is present in the form of phosphate salts in rocks and deep-sea sediments. Abiotic cycling of phosphorus takes millions of years because the processes of sedimentary rock formation, uplift, and weathering all take a long time. In contrast, phosphorus often cycles rapidly among organisms, and it is often a limiting factor for their growth, particularly for plants. Artificial fertilizers routinely include phosphorus as well as nitrogen.

Human activity has radically accelerated some parts of the phosphorus cycle. One consequence of the massive use of artificial fertilizers described above is that between 10.5 and 15.5 teragrams (1 tg = 10^{12} g or 10^9 kg) of phosphorus accumulate in

58.17 The Phosphorus Cycle The widths of the arrows are proportional to the sizes of the fluxes. Two large increases in phosphorus flux are the result of human activities.

soils each year, primarily in agricultural fields. When the concentration of phosphorus in soils exceeds the capacity of plants to take it up, the excess moves into streams and lakes. Soil erosion due to the clearing of land for purposes such as agriculture and logging also increases the amount of phosphorus and other nutrients in runoff. Phosphorus is a limiting nutrient in many lakes, so when it enters those lakes through runoff, eutrophication results, in much the same way that nitrate enrichment can cause eutrophication.

The capacity of phosphorus-charged runoff to cause extensive eutrophication was graphically illustrated almost 50 years ago. A technological innovation in the formulation of laundry detergents in the early 1960s was the use of sodium tripolyphosphate (STPP) ($\text{Na}_5\text{P}_3\text{O}_{10}$) as a water softener and dirt-breaking agent to enhance cleaning efficiency. Widespread adoption of these new detergents led to massive phosphorus enrichment of lakes and streams and resulting eutrophication and blooms of phytoplankton. Water quality declined so much across the United States that phosphate-based detergents were banned in many states. In today's detergents, phosphonates—forms of phosphorus that do not appear to promote algal growth—and aluminum silicates perform the functions STPP used to serve.

Detergents, however, are only one agent contributing to eutrophication. Human waste is rich in phosphorus, as are manure from domesticated animals and industrial wastes of various types. Two hundred years ago, Lake Erie, one of the Great Lakes on the border between the United States and Canada, had only moderate phytoplankton populations and clear, oxygenated water. With increasing industrialization in the early part of the twentieth century, nutrient concentrations in the lake increased greatly, and algae proliferated. At the water filtration plant in Cleveland, Ohio, algae increased from 81 individuals per milliliter in 1929 to 2,423 per milliliter in 1962. Populations of bacteria also increased; *Escherichia coli* levels rose so high that many of the lake's beaches were declared health hazards. Since 1972 the United States and Canada have invested more than U.S. \$9 billion to improve municipal waste treatment facilities and reduce discharges of pollutants. As a result, the amount of phosphorus added to Lake Erie has decreased more than 80 percent from its highest level, and phosphorus concentrations in the lake have declined substantially. The deeper waters of Lake Erie are still oxygen-poor during the summer months, but the rate of oxygen depletion is declining.

We could greatly reduce phosphorus pollution by recovering and recycling phosphorus. The phosphorus discarded in sewage and animal wastes could supply much of the needs of the detergent and fertilizer industries. More careful application of fertilizers on agricultural lands could reduce the rate of phosphorus accumulation in soils without reducing crop yields. However, reduction of phosphorus concentrations in soils will take many decades after remedial actions are initiated, and eutrophication of lakes and streams may persist even after these actions are taken.

Other biogeochemical cycles are also important

Other elements are important to the global ecosystem because they are essential nutrients for organisms, even though they are needed only in very small amounts. One such element is iron (Fe), an essential micronutrient for almost all organisms. Iron is a key component of the enzymes involved in chlorophyll synthesis as well as an essential component of many animal enzymes. Iron confers oxygen-binding ability on hemoglobin in vertebrate blood. Members of the cytochrome P450 family of enzymes, which in most aerobic organisms play a central role in detoxifying environmental poisons, rely on iron for their catalytic activity.

Iron is readily available on land in rocks and minerals. It moves into coastal waters in streams and into the open oceans in atmospheric dust. Because iron is insoluble in oxygenated water, it rapidly sinks to the ocean floor. Therefore in most marine communities the rate of photosynthesis is limited by iron. In 1996 investigators launched an ecosystem-scale experiment in which surface waters of the equatorial Pacific Ocean were seeded with dissolved iron. The response was a tremendous phytoplankton bloom, accompanied by massive uptake of nitrate and carbon dioxide, which had apparently been underused because of iron limitation.

Iodine is an example of an element that is globally rare but is an essential micronutrient for living organisms. Endothermic vertebrates in particular require iodine in concentrations that exceed the supply in many environments. It is an essential component of the hormone thyroxine, which governs many metabolic processes (see Section 41.4). Iodine is found on land in mineral deposits and in seawater as an inorganic salt.

Biogeochemical cycles interact

The biogeochemical cycles of different elements interact with one another in complex ways, and perturbations of one cycle can have profound effects on other cycles. In recent years, human-induced perturbations have made these interactions glaringly apparent. For example, nitrate released by human activities can have profound effects on the biogeochemical cycle of arsenic. The bottom sediments of some urban lakes contain arsenic levels in excess of 2,000 parts per million. Nitrate is a powerful oxidant, so nitrate pollution can increase the oxidation of arsenic in lake sediments, releasing it into the water in a form that is carcinogenic and has negative effects on embryonic development. Every year scientists discover interactions of which they were previously unaware, and studies exploring biogeochemical interactions are increasing in number.

Changes in atmospheric CO_2 concentrations have been a particular focus of investigation in recent years because of their potential for interacting with other biogeochemical cycles through photosynthesis. A case in point is a study of the effect of elevated atmospheric CO_2 concentrations on rates of nitrogen fixation by microorganisms associated with plant roots. Bruce Hungate and his colleagues grew a nitrogen-fixing vine (i.e., a legume) called Elliott's milkpea (*Galactia elliotii*) under

INVESTIGATINGLIFE

58.18 Effects of Atmospheric CO₂ Concentration on Nitrogen Fixation

Fixation Some scientists have hypothesized that rising concentrations of CO₂ in the atmosphere could lead to increased rates of photosynthesis, increased rates of nitrogen fixation, and eventually to the fixation of large amounts of carbon in the soil—which could potentially reduce global warming. In a 7-year-long experiment, Bruce Hungate and his colleagues at Northern Arizona University expected to find that nitrogen fixation in a leguminous vine would be enhanced by increased atmospheric CO₂.^a

HYPOTHESIS Exposure of legumes to elevated CO₂ concentrations will enhance nitrogen fixation by their symbiotic bacteria.

Method

Grow plots of the leguminous vine *Galactia elliptica* under baseline (typical) and artificially elevated concentrations of CO₂. Measure nitrogen fixation over 7 years.

Results

In an attempt to explain these results, (which did not support the hypothesis), the investigators measured the concentrations of iron and molybdenum—two micronutrients that are essential for nitrogen fixation—in the leaves of the 7-year-old plants.

CONCLUSION Although enhanced CO₂ levels initially increase nitrogen fixation, lowered levels of essential micronutrients in plants growing under these conditions soon leads to decreased rates of nitrogen fixation.

Go to **BioPortal** for discussion and relevant links for all INVESTIGATINGLIFE figures.

artificially increased CO₂ concentrations. Higher CO₂ concentrations led to an enhancement of nitrogen fixation during the first year of the experiment, but surprisingly, the positive effect disappeared by the third year, and elevated CO₂ concentrations actually *reduced* nitrogen fixation below baseline levels during the fourth, fifth, sixth, and seventh years of the experiment (**Figure 58.18**).

WORKING WITHDATA:

How Does Molybdenum Concentration Affect Nitrogen Fixation?**Original Paper**

Hungate, B. A. et al. 2004. CO₂ elicits long-term decline in nitrogen fixation. *Science* 304: 1291.

Analyze the Data

The experiments in Figure 58.18 were conducted in an oak woodland where *G. elliptica* grew naturally. The investigators used open-top chambers to produce a 350-ppm increase in the concentration of CO₂ in the air around the plants. The study site had a sandy, acidic soil known to have low concentrations of molybdenum.

Because nitrogen-fixing plants are sensitive to light availability, an alternative explanation for the results in Figure 15.18 is that increased shading resulting from greater leaf area of the CO₂-stimulated plants could have caused the subsequent decline in fixation. To test this possibility, the investigators computed the leaf-area index (LAI), a measure of the amount of leaf-surface area per unit of ground area. They found no correlation between LAI and nitrogen fixation, but they did find a positive correlation between concentrations of molybdenum in *G. elliptica* leaves and the rate of nitrogen fixation.

QUESTION 1

The authors claim that this regression analysis provides strong evidence in favor of low availability of molybdenum rather than low light availability as the reason for the decline in rate of nitrogen fixation. Do you agree? Why or why not?

QUESTION 2

What does this experiment suggest about the kinds of future studies and the range of ecosystem types and nutrient elements that should be investigated to determine the likely overall response of Earth's ecosystems to increasing atmospheric concentrations of CO₂?

Go to **BioPortal** for all WORKING WITHDATA exercises

The investigators suspected that a lack of micronutrients such as iron and molybdenum had caused the reduction in nitrogen fixation, so they measured concentrations of those elements in the leaves of the *G. elliptica* grown under high CO₂ concentrations. They found that concentrations of molybdenum in those plants were particularly low. Hungate and his

colleagues proposed a mechanism by which this could occur: elevated CO₂ concentrations could increase the acidity of water in soil by enhancing the rate of carbonic acid formation. By enhancing photosynthesis, elevated CO₂ concentrations could increase the accumulation of organic matter in the soil. Both types of change would increase the tendency of iron and molybdenum to bind to soil particles, which would reduce their availability to nitrogen-fixing bacteria and cause a decrease in nitrogen fixation rates.

RECAP 58.3

The pattern of movement of a chemical element through the biotic and abiotic compartments of the global ecosystem is its biogeochemical cycle. Human activities have affected many biogeochemical cycles, especially those of water, carbon, nitrogen, sulfur, and phosphorus. Increasing concentrations of carbon dioxide and other greenhouse gases in the atmosphere are implicated in global climate change.

- Describe the global hydrologic cycle and explain what drives it. **See p. 1215 and Figure 58.9**
- How do biological processes move carbon from the atmosphere to land and then return it to the atmosphere? **See p. 1216 and Figure 58.10**
- What are some results of human-induced alterations of the sulfur and nitrogen cycles? **See pp. 1219–1221**
- Name two elements that can cause eutrophication in aquatic ecosystems and describe their effects on those systems. **See pp. 1219 and 1221**

The biogeochemical cycles of chemical elements are intimately involved in ecosystem function. Just as human alterations of those cycles are having many effects on ecosystems worldwide, the resulting changes in those ecosystems are having profound effects on human lives.

58.4 What Goods and Services Do Ecosystems Provide?

Although it seems obvious today that humans depend on natural ecosystems for survival, explicit recognition of the value of those ecosystems is rather recent. Environmental writers introduced the idea of “natural capital” in the 1940s; it was in 1970 that ecosystems were first said to provide people with a variety of “goods and services.” The goods include food, clean water, clean air, fiber, building materials, and fuel; the services include flood control and water quality, soil stabilization, pollination, and climate regulation. Most of these benefits either are irreplaceable, or the technology necessary to replace them is prohibitively expensive. For example, fresh drinking water can be provided by desalinating seawater, but only at great cost. The aesthetic, psychological, spiritual, and recreational benefits of ecosystems are less tangible, but no less important, and no more easily replaced.

Humans have increasingly altered Earth’s ecosystems in ways that increase the systems’ capacity to provide us with necessities such as food, fresh water, timber, fiber, and fuel. The

benefits of these ecosystem alterations have not been equally distributed, and some human populations have been harmed by manipulations of natural ecosystems. Moreover, short-term increases in some ecosystem goods and services often comes at the cost of the long-term degradation of others.

Although humans have been altering natural ecosystems for millennia, the pace and scope of the shift to intense human use have increased considerably in the past century. More land was converted to cropland between 1950 and 1980 than in the 150 years between 1700 and 1850. Ecosystem conversions have been particularly rapid in tropical and subtropical biomes. Aquatic ecosystems have suffered losses at an increasing pace as well. In freshwater ecosystems, so much water is now impounded behind dams that artificial reservoirs hold about six times as much water today as do natural rivers. These freshwater systems are being rapidly depleted: the amount of water withdrawn from rivers—most of it for agriculture—has doubled since 1960. In terms of nutrient cycling, more than half of all the artificial nitrogen fertilizer ever used on Earth has been used since 1985.

Human alteration of ecosystems has had many positive effects on human health and prosperity, but it necessarily involves trade-offs. Agriculture, for example, feeds and employs huge numbers of people. But the spread of agriculture into marginal lands may degrade soils and compromise the ability of ecosystems to provide clean water, as when overuse of artificial fertilizers results in eutrophication. Extensive use of pesticides controls insect pests, but also reduces populations of pollinators and the services they provide to both crops and native plants.

Similarly, the loss of wetlands and other natural buffers has reduced the ability of ecosystems to regulate flooding and other natural hazards. The damage from the tsunami that hit Indonesia and other Southeast Asian countries in December 2004 was greater in many places than it would have been had the mangrove forests that protect the coast not been cut down and converted to cropland. Hurricane Katrina, which struck the U.S. Gulf Coast less than a year later, would not have caused as much flooding in New Orleans had the wetlands surrounding the city been intact. Katrina’s devastating effects were due in part to a situation that had been developing for decades.

New Orleans is located on the Mississippi River delta. Much of the city lies below sea level, buffered by dams and levees constructed by the Army Corps of Engineers. The upstream dams that protect New Orleans from flooding also prevent the river from depositing the sediments that have sustained the surrounding delta wetlands for centuries. Oil and natural gas producers have cut thousands of small canals through those wetlands in order to lay pipelines and install drilling rigs, and the extraction of oil and gas from beneath the land has caused it to sink. Increased dredging of shipping lanes and rising sea levels due to global warming have contributed to a rise in salinity, killing off many of the great cypress tree swamps. These extensive alterations resulted in the loss of more than 80 percent (more than 50,000 hectares, or 1.2 million acres) of the delta wetlands between 1930 and 2005. By the time Katrina made landfall, those wetlands could

no longer protect New Orleans from flooding. Storm surges raced along the paths carved by canals and shipping lanes to breach the levees, inundating much of the city.

As it flooded New Orleans, Hurricane Katrina raised awareness and appreciation of an ecosystem hitherto taken for granted by most people. Crucial not only for their flood control services, the delta wetlands provide winter habitat for some 70 percent of the migrating birds in the huge Mississippi Valley. They are also the spawning grounds for marine organisms, some of which are commercially valuable. The delta's famous shrimping industry contributes about 30 percent by weight of the total commercial fish harvest in the continental United States. The importance of coastal wetlands—and, indeed, of a wide range of other ecosystems—to human well-being mandates careful ecosystem management to guarantee a sustained flow of ecosystem goods and services.

RECAP 58.4

Ecosystems provide human society with indispensable goods and services. Altering ecosystems can compromise their ability to provide these goods and services.

- What are some of the essential goods and services that ecosystems provide to humans? [See p. 1223](#)
- Give an example of a human effort to increase the provision of some ecosystem goods or services that caused the degradation of others. [See p. 1223](#)

How can we meet the challenge of obtaining goods and services from ecosystems without compromising their ability to provide those goods and services over the long term? What options exist for sustainable management of ecosystems?

58.5

How Can Ecosystems Be Sustainably Managed?

Practices that allow us to conserve or enhance ecosystems so as to benefit from specific ecosystem goods and services over the long term without compromising others are referred to as **sustainable**. In many cases the total economic value of a sustainably managed ecosystem is higher than that of a converted or intensively exploited ecosystem (**Figure 58.19**). Furthermore, the long-term economic benefits of preventing overexploitation of ecosystems are enormous. For example, the collapse of the cod fishery on Georges Bank due to overfishing (see **Figure 55.14**) resulted in the loss of tens of thousands of jobs.

Impeding the establishment of policies that encourage sustainable practices is the impression that ecosystem services are “public goods” with no market value. People who do not stand to profit from the services provided by natural ecosystems have no incentive to pay for them, whereas individuals who own converted ecosystems can reap great economic benefits. Government action may be needed to create incentives encouraging sustainable ecosystem management. Examples of such action might include:

- Elimination of subsidies that promote damaging exploitation of ecosystems. For example, the billions of dollars

58.19 The Economic Value of Sustainably Managed Ecosystems

Many types of ecosystems are able provide more goods and services when they are sustainably managed than when they are completely converted to human use and intensively exploited.

paid by governments in developed nations to subsidize domestic agriculture (with the aim of insulating farmers from economic risk) have led to greater food production than the global market warrants, promoted excessive use of fertilizers, and reduced the profitability of agriculture in developing countries.

- More sustainable use of fresh water from rivers and aquifers could be achieved by charging users the full cost of providing water, by developing methods to use water more efficiently, and by altering the allocation of water rights so that the incentives favor conservation rather than wasteful consumption.
- More sustainable use of marine fisheries could be achieved by establishing more protected marine reserves and “no-take” zones where fish can grow to reproductive age. Recent discussions of marine fisheries management center on what is colloquially known as the BOFFF (“Big, Old, Fat, Female Fish”) hypothesis, which proposes that it is most important to protect the largest and oldest females in a population because they outreproduce younger fish by an enormous margin (see **Section 55.6**).

Raising public awareness is essential to the implementation of sustainable management programs. Most people do not realize the long-term value of ecosystem goods and services or understand how human activities affect the functioning of ecosystems. Maintaining and enhancing ecosystem goods and services that have no established market value is especially difficult. Perhaps the most difficult aspect of ecosystem function to maintain in the face of increasingly intensive human use of the global ecosystem will be biological diversity. The final chapter of this book is devoted to this important topic.

How can we determine to what extent dead zones result from human actions and to what extent they are the result of natural biogeochemical processes?

ANSWER

Hypoxia occurs naturally in aquatic systems, but throughout history it has been restricted primarily to deep-water ecosystems such as deep ocean basins, fjords, and the bottoms of the largest lakes. The appearance of dead zones in shallow coastal waters and estuaries is a twentieth-century phenomenon (the Gulf of Mexico dead zone was first identified in 1972). This timing, as well as the observation that dead zones are increasing in number and size, suggests human involvement.

The White House Office of Science and Technology Policy's Committee on Environment and Natural Resources initiated a scientific assessment of the causes and consequences of Gulf hypoxia in 1997. As part of this effort, sediment cores were tak-

en to determine historic levels of algal deposition in sediment. These cores revealed a clear pattern of increases in the second half of the twentieth century. Sophisticated computer models demonstrated a significant association between river loads of dissolved inorganic nitrogen and rates of oxygen depletion, and the most dramatic increases coincided with historic records of changes in human activities that increased nitrate loads in the river system. Given that the Gulf of Mexico provides almost three-fourths of the shrimp and two-thirds of the oysters harvested in the U.S., as well as recreational fishing resources and ecologically vital forage fishes, further expansion of the dead zone could have devastating economic consequences.

CHAPTER SUMMARY 58

58.1 How Does Energy Flow through the Global Ecosystem?

- An **ecosystem** includes all of the organisms in an ecological community as well as the physical and chemical factors that influence those organisms.
- Energy flows and chemical elements cycle through ecosystems. **Review Figure 58.1**
- Terrestrial net primary production varies across the globe, reflecting differences in solar energy input and the climate patterns that result from them. **Review Figures 58.2, 58.3**
- Productivity in aquatic ecosystems is limited by light, temperature, and nutrient availability. **Review Figure 58.4**
- Humans appropriate about one-quarter of Earth's average annual net primary production, although this amount varies regionally.

58.2 How Do Materials Move through the Global Ecosystem?

- Chemical elements cycle through biotic and abiotic compartments of the global ecosystem. **Review Figure 58.5**
- The movement of elements through the biotic compartment of ecosystems, from uptake by autotrophs to decomposition, generally occurs on a local scale.
- Most global air circulation takes place in the lowest layer of the atmosphere, the **troposphere**. An **ozone layer** in the **stratosphere** absorbs ultraviolet radiation. **Review Figure 58.6**
- Carbon dioxide, water vapor, and other **greenhouse gases** in the atmosphere are transparent to sunlight but trap heat, thus warming Earth's surface. **Review Figure 58.7, ANIMATED TUTORIAL 58.1**
- Because the geological processes that move elements on land are so slow (on the scale of millions of years), there are large regional and local variations in the supply of particular elements within the terrestrial compartments.
- Some nutrients enter fresh waters from the atmosphere in rainfall, but most are released from rocks by weathering. They are usually carried rapidly to lakes or to the oceans.
- **Turnover** occurs regularly in temperate-zone lakes in both spring and fall, bringing nutrients to the surface and oxygen to the deeper waters. **Review Figure 58.8**

- Most materials that cycle through biotic and abiotic compartments end up in the oceans, where they eventually sink to the bottom.
- Fires release the chemical elements from the vegetation they burn. Those vaporized elements enter the atmosphere, where they can be carried into groundwater by rain.

58.3 How Do Specific Nutrients Cycle through the Global Ecosystem?

- The pattern of movement of a chemical element through the biotic and abiotic compartments of the global ecosystem is its **biogeochemical cycle**.
- The **hydrologic cycle** is driven by the sun, which evaporates more water from the ocean surface than it returns by precipitation. The excess precipitation that falls on land eventually returns to the oceans, primarily in rivers. **Review Figure 58.9, ANIMATED TUTORIAL 58.2**
- Groundwater plays a minor role in the hydrologic cycle, but underground **aquifers** are being seriously depleted by human activities.
- Carbon is removed from the atmosphere by photosynthesis and returned to the atmosphere by metabolism and burning. **Review Figure 58.10, ANIMATED TUTORIAL 58.3**
- The concentration of CO_2 in the atmosphere has increased greatly in the last 150 years, largely because of the burning of fossil fuels. This buildup of CO_2 is warming the global climate. **Review Figures 58.11–58.13**
- As a result of agricultural use of fertilizers and the burning of fossil fuels, total nitrogen fixation by humans is nearly equal to natural nitrogen fixation. **Review Figures 58.14, 58.15, ANIMATED TUTORIAL 58.4**
- Human alteration of the nitrogen cycle has resulted in excesses of nitrogen compounds in bodies of water, leading to **eutrophication** and dead zones.
- The burning of fossil fuels releases sulfur and nitrogen into the atmosphere, leading to **acid precipitation**. **Review Figure 58.16**
- Agricultural use of fertilizers and clearing of land have dramatically increased the input of phosphorus into soils and fresh waters. **Review Figure 58.17**

continued

58.4

What What Goods and Services Do Ecosystems Provide?

- The goods and services provided by ecosystems include food, clean water, flood control, pollination, pest control, climate regulation, spiritual fulfillment, and aesthetic enjoyment. Most ecosystem services either are irreplaceable or the technology necessary to replace them is prohibitively expensive.
- Efforts to enhance the capacity of an ecosystem to provide some goods and services often come at the cost of the system's ability to provide others.

58.5

How Can Ecosystems Be Sustainably Managed?

- The total economic value of an ecosystem managed in a **sustainable** manner often is higher than that of a converted or intensively exploited ecosystem. **Review Figure 58.19**
- Recognition of the value of ecosystem goods and services that are now perceived as "public goods" may induce government action to protect them. Public education is needed to make people aware of how much they benefit from ecosystem goods and services.

CHAPTER REVIEW**REMEMBERING**

1. What features of Earth influence its ecosystem dynamics?
 - a. Lithospheric plates that move continuously
 - b. Atmospheric gases that moderate surface temperatures
 - c. Large amounts of water in liquid form
 - d. A diversity of living organisms
 - e. All of the above
2. Marine upwelling zones are important because
 - a. they help scientists measure the chemistry of deep ocean waters.
 - b. they bring to the surface organisms that are difficult to observe elsewhere.
 - c. ships can sail faster in these zones.
 - d. they increase marine productivity by bringing nutrients back to surface ocean waters.
 - e. they bring oxygenated water to the surface.
3. The hydrologic cycle operates as it does because
 - a. water flows into the oceans via rivers.
 - b. water evaporates from the leaves of plants.
 - c. more water evaporates from the surface of the oceans than is returned to the oceans as precipitation.
 - d. precipitation falls on land.
 - e. more water falls on the oceans as precipitation than evaporates from its surface.
4. Carbon dioxide is called a greenhouse gas because
 - a. it is used in greenhouses to increase plant growth.
 - b. it is transparent to heat but traps sunlight.
 - c. it is transparent to sunlight but traps heat.
 - d. it is transparent to both sunlight and heat.
 - e. it traps both sunlight and heat.

5. The biogeochemical cycle of phosphorus differs from the cycles of carbon and nitrogen in that
 - a. phosphorus lacks an atmospheric component.
 - b. phosphorus lacks a liquid phase.
 - c. only phosphorus is cycled through marine organisms.
 - d. living organisms do not need phosphorus.
 - e. The phosphorus cycle does not differ importantly from the carbon and nitrogen cycles.
6. Maintaining the capacity of ecosystems to provide goods and services is important because
 - a. most ecosystem services cannot be replicated by any other means.
 - b. replacing them with technological substitutes is prohibitively expensive.
 - c. technological substitutes take up valuable land.
 - d. governments cannot function without taxing ecosystem services.
 - e. It is not important. Humans could survive quite well even if ecosystem services declined greatly.

UNDERSTANDING & APPLYING

7. The waters of Lake Washington, the second largest lake in the state of Washington and lying adjacent to the city of Seattle, returned to their preindustrial condition within 10 years after sewage was diverted from the lake to Puget Sound, an arm of the Pacific Ocean. Would all lakes being polluted with sewage clean themselves up as quickly as Lake Washington if sewage inputs were stopped? What characteristics of a lake are most important to its rate of recovery following reduction of nutrient inputs?
8. A government official authorizes construction of a large coal-burning power plant in a former wilderness area. Its smokestacks discharge great quantities of combustion wastes. List and describe all the likely effects of this action on ecosystems at local, regional, and global levels. If the wastes were thoroughly scrubbed from the stack gases, which of the effects you have just outlined would still happen?

ANALYZING & EVALUATING

9. What types of experiments would you conduct to assess the likely consequences of fertilization of the oceans with iron to increase rates of photosynthesis? At what spatial and temporal scales should these experiments be conducted?
10. One mechanism proposed for reducing the anthropogenic (human-caused) flux of carbon into the atmosphere is called “cap and trade,” whereby a government sets a “cap,” or limit, on carbon emissions by polluters, but allows facilities that emit less than their emission allowance to sell their excess credits to polluters who would otherwise exceed their emission allowance. What benefits and drawbacks can you see to such an approach to reducing carbon emissions?
11. A string of powerful hurricanes struck the east coast of the United States over the course of a single year’s hurricane season. Some people claim that this disaster was due to warming of the oceans caused by greenhouse gases in the atmosphere. Others assert that global warming is not responsible because hurricanes have occurred for many centuries. How would you evaluate these conflicting claims?

Biodiversity and Conservation Biology

CHAPTER OUTLINE

- 59.1** What Is Conservation Biology?
- 59.2** How Do Conservation Biologists Predict Changes in Biodiversity?
- 59.3** What Human Activities Threaten Species Persistence?
- 59.4** What Strategies Are Used to Protect Biodiversity?

A Natural Christmas Tree During the 1980s, large numbers of migrating bald eagles (*Haliaeetus leucocephalus*) turned Montana's Glacier National Park into a tourist attraction each fall as the birds stopped to feed on spawning kokanee salmon. When the salmon population fell victim to introduced lake trout, the eagles also disappeared and tourism declined.

MANY HUMAN ACTIVITIES have factored in the extinction of animal species; even good intentions can pose a threat. Flathead Lake in northwestern Montana originally had fewer than a dozen native fish species, including bull trout (*Salvelinus confluentus*) and westslope cutthroat trout (*Oncorhynchus clarkii lewisi*). To encourage sport fishing, non-native sport fish species were introduced. Most of these introductions were unsuccessful, but the kokanee salmon (*Oncorhynchus nerka*), introduced from western Canada, eventually prospered and by the mid 1980s was the dominant sport fish.

Because kokanee were popular with anglers, efforts were made to establish them in nearby lakes. Fisheries managers introduced opossum shrimp (*Mysis diluviana*) into neighboring lakes to provide a food source for juvenile kokanee, which feed on zooplankton. But kokanee are daytime feeders that use vision to find their prey; opossum shrimp remain on lake bottoms during the day, thus escaping predation by the young kokanee.

Somehow the shrimp made their way to Flathead Lake, where they proved to be a bonanza for lake trout (*Salvelinus namaycush*), another introduced species but one that had never become abundant because of limited food supply on the lake bottom, where the trout feed as juveniles. With the new food source, the lake trout population exploded. Adult lake trout are voracious consumers of other fish, and kokanee numbers plummeted as they fell prey to the lake trout. By 1992 kokanee were gone from Flathead Lake. The native bull trout may be next; this species was officially designated "vulnerable to extinction" in 1999 and its future is uncertain.

These changes have had economic impacts well beyond sport fishing. In the 1980s, flocks of migrating bald eagles gorged on the abundant kokanee spawning upstream of Flathead Lake in Glacier National Park. The sight was a tremendous tourist draw every fall. Without the salmon, fewer eagles visit the area, and without the eagles, there are fewer tourists. This example of unanticipated effects of human activities is far from unique. Given what we know about species interactions, it should not be surprising that a species introduced in the wrong place can endanger other species.

How can adverse impacts of species introductions be anticipated before lasting damage occurs?

See answer on p. 1245.

59.1 What Is Conservation Biology?

Virtually all natural ecosystems on Earth have been altered by human activities. Many habitats have disappeared completely, and many others have been greatly modified. Even Earth's climate and its global biogeochemical cycles have been altered, as we saw in Chapter 58. One consequence of these changes has been a rapid increase in the rate at which species go extinct.

Conservation biology is a scientific discipline devoted to protecting and managing Earth's biodiversity. The discipline draws heavily on the principles of ecology, ethology, evolutionary biology, and wildlife management particularly when elucidating the factors that determine whether a given population will persist.

Early conservation efforts were characterized by tensions between people whose principal goal was to conserve natural resources for their economic benefits and people who believed that nature has intrinsic value independent of human economic interests. Today conservation biologists study the full array of goods and services that humans derive from species and ecosystems, including aesthetic and psychological benefits. We now know that understanding the global ecosystem and the effects of human activities on that system is essential to the long-term well-being of *Homo sapiens*.

Conservation biology is an applied discipline, which is to say that it involves the practical application of scientific knowledge to solve problems. Workers in conservation biology are guided by three basic principles:

- *The processes of evolution unite all forms of life.* To effectively protect and manage biodiversity, we must understand the evolutionary processes that generate and maintain it.
- *The ecological world is dynamic.* Because populations and communities change continuously over time, there is no static “balance of nature” that can serve as a goal of conservation activities.
- *Humans are a part of ecosystems.* Human interests and activities must be incorporated into conservation goals and practices.

Conservation biology aims to protect and manage biodiversity

The term **biodiversity**, a contraction of “biological diversity,” has multiple definitions. We may speak of biodiversity as the degree of genetic variation within a species. Genetic variation can be measured as the number of alleles at a locus, the number of polymorphic loci in a genome, or the number of individuals in a population that are polymorphic at given loci. As we have seen throughout this book, genetic variation allows organisms to adapt to environmental change. Biodiversity can also be defined in terms of species richness in a particular community. At

59.1 Extinct Megafauna The extinction of some large North American mammals during the Pleistocene may have been driven by the arrival of *Homo sapiens*. This portion of a museum re-creation shows Columbian mammoths (*Mammuthus columbi*), ancient bison (*Bison antiquus*, an extinct ancestor of the American bison) and western horses (*Equus occidentalis*).

a larger scale, biodiversity also embraces ecosystem diversity—particularly the complex interactions within and between ecosystems. While we may study these components of biodiversity separately, in life they are intimately interconnected.

One conspicuous manifestation of biodiversity loss is species extinction. Extinction is a constant theme in the history of life; most of the species that have lived on Earth over the ages are extinct today. Consider, for example, the anaerobic organisms that were lost as early photosynthetic prokaryotes and eukaryotes added oxygen to Earth's atmosphere, as described in Section 25.2. Extinctions have occurred throughout Earth's history at what is referred to as a “background” rate as changes in environmental conditions have favored some species and negatively affected others. But the rate of extinctions taking place today rivals those of the five great mass extinctions (see Table 25.1 and Figure 25.2). The past mass extinction episodes were the result of cataclysmic natural disturbances, whereas the majority of modern extinctions can be attributed to effects of human activities.

Humans have a tremendous capacity to alter ecosystems and, accordingly, to cause extinctions. When humans first arrived in North America from Siberia about 14,000 years ago, they encountered a diverse and spectacular fauna of large mammals, including saber-toothed cats, dire wolves, mammoths, mastodons, giant ground sloths, and giant beavers (**Figure 59.1**). Most of this megafauna went extinct within a few thousand years after humans arrived. Although several hypotheses have been advanced to account for the geologically rapid and simultaneous disappearance of so many large animals, overhunting by humans is the most likely explanation. Losses of megafauna coinciding with the arrival of humans have also been documented in Australia and Hawaii.

Over the past 400 years, increasing industrialization and urbanization have accelerated the rate of species extinctions astronomically. The renowned evolutionary biologist Edward O. Wilson estimates that Earth is losing some 30,000 species

per year, putting us in the midst of a sixth mass extinction. The mass extinction events in Earth's past occurred relatively far apart in time, and each one provided ecological opportunities for other groups, which subsequently underwent adaptive radiations. Protecting Earth's biodiversity today requires maintaining the processes that generate new species as well as bringing extinction rates closer to background levels.

Biodiversity has great value to human society

Conservation biologists are concerned about the escalating loss of Earth's biodiversity for many reasons:

- *Humans depend on thousands of other species for food, fiber, and medicine.* Humans have domesticated countless plants as sources of food, and more than 2,000 plant species are used for fiber worldwide. In India alone, more than 7,000 species of plants are used in traditional medicine, and in the United States more than one-fourth of all medical prescriptions contain or are based on plant products. Hundreds of animal species also supply us with food, clothing, and medicine.
- *Losing species can threaten ecosystem functioning.* Throughout Part 10 we have described many complex interactions among species. When species are lost, entire communities and ecosystems may change or be lost completely and humans may lose the goods and services those ecosystems provide.
- *Humans derive enormous psychological benefits, including aesthetic pleasure, from interacting with other organisms.* These aesthetic benefits give biodiversity economic value. Trees growing on a residential lot, for example, can increase the lot's property value by an amount that is greater than the value of the lumber that could be made from the trees.
- *Extinctions deprive the scientific community of opportunities to study and understand ecological relationships among organisms.* The more species that are lost, the more difficult it will be to understand the structure and functioning of ecological communities and ecosystems.
- *Living in ways that cause the extinction of other species raises ethical issues.* Losses of biodiversity increasingly concern philosophers, ethicists, and religious leaders, who believe species to have intrinsic value.

All of these concerns, to varying degrees, may be integrated by conservation biologists into strategies for protecting biodiversity.

RECAP 59.1

Conservation biology is an applied scientific discipline aimed at protecting and managing biodiversity, which is rapidly decreasing due to extinctions that are the result of human activities.

- Explain the multiple meanings of the term "biodiversity." **See p. 1229**
- What are some of the ways in which biodiversity is valuable to humans? **See p. 1230**

Conservation biologists must understand biodiversity as it exists today as well as how and why it is changing. An important

goal of conservation biologists is to predict which species are most likely to go extinct and how soon extinction is likely to happen.

59.2 How Do Conservation Biologists Predict Changes in Biodiversity?

How many, and which, species will go extinct will depend both on human activities and on natural events. Conservation biologists attempt to track the extinctions that are occurring and to predict the ones that are likely to occur during the coming century.

Our knowledge of biodiversity is incomplete

Tracking and predicting extinctions is difficult for several reasons. First, we do not know how many species live on Earth today. Many species that are likely to go extinct in the near future have not even been named and described by scientists. Insects provide a case in point: although more than 1 million species have been described (see Section 32.4), estimates of the number of species yet to be discovered range from 2 million to more than 50 million. Even in the case of larger organisms, our understanding of biodiversity is far from complete. For example, in an 18-month period in 2005–2006, more than 50 species of animals and plants previously unknown to science were discovered in the rainforests of Borneo. Worldwide, an annual inventory of newly described species counted 19,232 species discovered in 2009 alone; this list included 9,738 insects, 2,184 plants, 1,360 fungi, 71 mammals, and 7 birds.

Second, we do not know where species live. The ranges of most described species, particularly those that are small, reclusive, and rare to start with, are poorly known. One tiny North American true bug, *Corixidea major* (so rare that it has no common name), had been found in only one location near Clarksville, Tennessee, until entomologists collecting insects attracted to lights at night discovered it in Virginia and Florida, extending its known range by more than 1,000 kilometers.

Third, it is difficult to determine whether a species is truly extinct. Rarely is the death of the last surviving member of a species recorded with certainty, as it was in the case of the last passenger pigeon (*Ectopistes migratorius*), a female named Martha, who died in the Cincinnati Zoo on September 1, 1914. The status of rare, reclusive species with poorly known life histories is much more difficult to determine, as has been the case with the ivory-billed woodpecker (*Campephilus principalis*) in the southeastern United States, which is thought to be extinct despite reported sightings (**Figure 59.2A**). Pygmy tarsiers (*Tarsius pumilus*), tiny primates weighing less than 60 grams, were thought to have gone extinct from their native cloud forests on the island of Sulawesi in Indonesia. In 2008—85 years after the last reported sighting of a living *T. pumilus*—a research team from Texas A&M University discovered individuals of this species living in one of the island's national parks (**Figure 59.2B**).

Fourth, we rarely know all of the connections among species. At the opening of this chapter, we saw how the introduction

(B) *Tarsius pumilus*

59.2 Is It Really Extinct? (A) The ivory-billed woodpecker (shown here in a nineteenth-century Audubon print) was presumed to be extinct until reports of sightings in 2004. Clear proof of the living bird has so far eluded ornithologists. (B) In 2008, pygmy tarsiers were discovered in an Indonesian national park after having been presumed extinct for 85 years.

of one non-native species altered Flathead Lake's entire food web and placed other species at risk. How many species are at risk is unknown, however, because the ecological interactions among all of the lake inhabitants have never been thoroughly characterized.

We can predict the effects of human activities on biodiversity

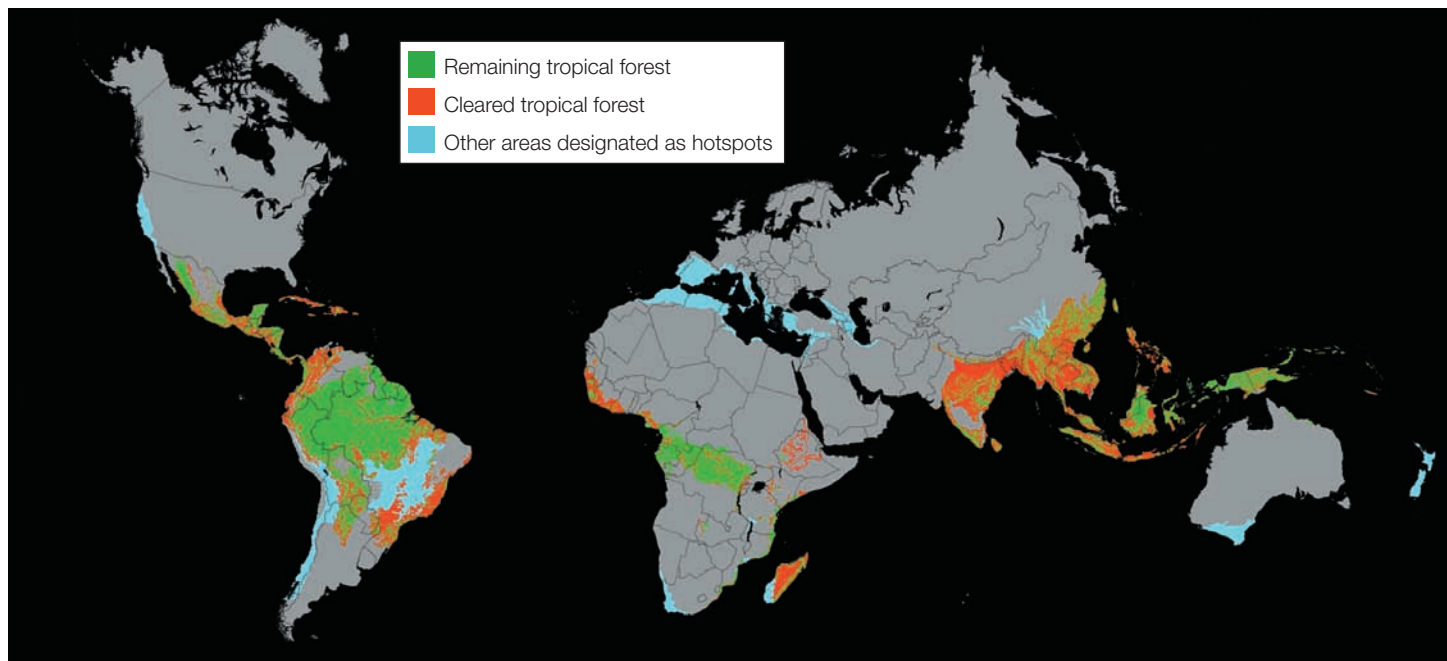

Despite these gaps in our understanding of biodiversity, methods exist for estimating probable rates of extinction resulting from human activities. To estimate the risk that a particular population will become extinct, conservation biologists develop statistical models that incorporate information about a population's size, its genetic variation, its life history traits, and the physiology and behavior of its members. The International Union for the Conservation of Nature (IUCN) has published categories that define a species' danger of extinction. Species in imminent danger of extinction in all or most of their range are classified as "endangered" or "critically endangered"; those believed to be susceptible to extinction in the near future are classified as "vulnerable." Biologists consider species in any one of these three categories to be "threatened" (Figure 59.3).

59.3 Species at Risk of Extinction (A) The breakdown by extinction risk category of all 47,677 species assessed by the IUCN. (B) The bars show the numbers and proportions of species in the various extinction risk categories (together termed "threatened") in several taxonomic groups that have been comprehensively assessed.

Rarity in and of itself is not always a cause for concern. Some species that are specialized for living exclusively in rare and unusual habitats have probably never been especially abundant and are well adapted to being rare. The Cayman crab fly (*Drosophila endobranchia*), for example, has probably never been abundant. It is found only in the Cayman Islands, where it parasitizes only two species of terrestrial crabs. Small population sizes are of concern, however, especially for species whose populations shrink suddenly. These "newly rare" species are usually at high risk of extinction, as large and rapid reductions in population size can lead to genetic drift and loss of genetic variation (see Chapter 21).

Certain aspects of species' life histories are particularly important in predicting the ability of populations to recover from reductions in size (see Chapter 55). In fishes and mammals, for example, one of the best predictors of extinction risk is age at maturity, a life history trait that has a profound influence on rates of population growth. Ecological niche requirements can also influence the ability of populations to recover from rapid declines. Species with specialized habitat or dietary requirements, for

59.4 The Disappearing Rainforest Since around 1950, tropical forests have been destroyed at tremendous rates as land is cleared for agriculture, highways, timber resources, and other needs of an

exploding human population. Rainforests have long been recognized as centers of biodiversity, or “hotspots,” that harbor vast numbers of species (see Section 59.4 and Figure 59.10).

example, are more likely to become extinct than species with more generalized requirements.

In addition, populations reduced to a small size or confined to a small range can easily be eliminated by local disturbances. For example, populations of the Cozumel thrasher (*Toxostoma guttatum*), a member of the mockingbird family known only on the island of Cozumel off the coast of Mexico, had been declining since 1970 due to a combination of factors, including the unintentional introduction of boa constrictors to the island. Then, beginning in 1988, a series of strong hurricanes had a catastrophic effect on the remaining thrasher populations. Surveys done in 2006 failed to document any surviving individuals, and today *Toxostoma guttatum* is most likely extinct.

Conservation biologists apply the principles of the species–area relationship and the theory of island biogeography (see Section 57.3) to predict the effects on species of habitat loss—the major cause of extinction today. By measuring the rate at which species richness decreases with decreasing habitat patch size, they have found that, on average, a 90 percent loss of habitat area results in the loss of half the species that live in and depend on that habitat. We will examine a key example of such a study in Section 59.3.

Similar calculations can be made for the total global area of a habitat type. The current rate of loss of tropical rainforest—Earth’s most species-rich biome—is about 2 percent of the remaining forest each year due to the increasing demands of a rapidly expanding human population not only for forest resources but also for cleared agricultural land. Most of the rainforests of Asia have already been reduced to small fragments, the only extensive tracts remaining being found on the islands of New Guinea and, to a much lesser extent, Borneo (Figure 59.4). Between 2000 and 2010, the highest rate of

tropical deforestation took place in Central America. If the current rate of loss continues, close to 1 million rainforest species (a conservative estimate) could become extinct before the end of this century.

RECAP 59.2

Predicting changes in biodiversity is difficult because our knowledge of biodiversity is incomplete. The species–area relationship can be used to predict rates of extinction in areas that are subject to habitat loss.

- What are some of the gaps in our current knowledge of biodiversity? [See pp. 1230–1231](#)
- What are some of the factors that render a species especially vulnerable to extinction? [See pp. 1231–1232](#)

Many factors can place species at risk of extinction, but human activities have had a disproportionate impact on the mass extinction that Earth is currently experiencing. Understanding how particular human activities present challenges to species survival is essential for developing ways to mitigate biodiversity losses.

59.3

What Human Activities Threaten Species Persistence?

Human activities that threaten the persistence of species include habitat alteration and destruction, introductions of non-native species, overexploitation, and climate alteration. Conservation biologists determine how these activities affect species and use that information to devise strategies to protect species that are endangered or threatened.

Habitat losses endanger species

Global Biodiversity Outlook 3, a report published by the United Nations in 2010, identified five principal pressures on biodiversity. Topping the list is habitat loss and degradation, including fragmentation or outright destruction of habitat by human activities.

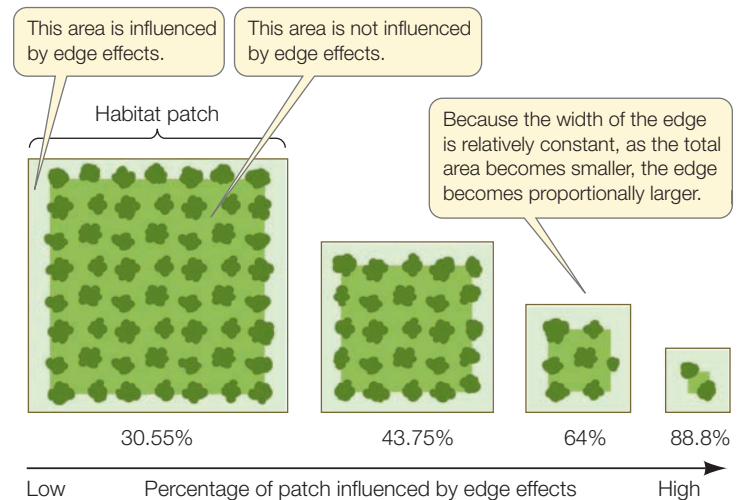

Many habitats—particularly freshwater habitats—are being degraded by pollution. Many toxic substances released into natural habitats by human activities have negative effects on the reproduction, development, and behavior of species, reducing both their survivorship and their competitive ability. Among the most troublesome toxic pollutants today are heavy metal waste products of mining and manufacturing, polycyclic aromatic hydrocarbons arising from fossil fuel combustion, and synthetic organic chemicals released into the environment to control pests.

Pollutants do not necessarily have to be toxic to cause problems. Nondegradable plastic trash dumped in the ocean poses a choking hazard to marine birds and mammals, which can mistake floating bits of plastic for prey that they then try to eat. Fish, corals, and other sea life can become entangled in discarded plastic, often resulting in their death.

Habitat loss can also occur through outright habitat elimination. As we saw in Section 58.4, natural ecosystems are being converted to human use at an increasing rate. Physical destruction of a particular habitat, as when tropical rainforest is cut down and the land converted to agricultural use, eliminates species that cannot survive anywhere else. Habitat loss also affects nearby habitats that are not destroyed. As portions of a habitat are lost to human activities, the remaining habitat becomes **fragmented** into habitat patches that become ever smaller and more isolated.

Small habitat patches are qualitatively different from larger patches of the same habitat in ways that affect species persistence. Small patches cannot maintain populations of species that require large areas, and they can support only small populations of those species that can survive in small patches. In addition, the fraction of a patch influenced by external factors increases disproportionately as patch size decreases (**Figure 59.5**). Close to the edges of a forest patch, winds are stronger, temperatures are higher, humidity is lower, and light levels are higher than they are farther inside the forest. Species from surrounding habitats often colonize the edges of a patch, where they compete with or prey on the species living in the patch. These influences are known as **edge effects**. A proliferation of edges can benefit some species, such as those that depend on resources in multiple habitats and must travel among them. For many other species, however, edge effects render habitats unsuitable or promote the establishment of competitors, predators, or parasites.

One effect of forest fragmentation in midwestern North America has been an increase in the abundance of the brown-headed cowbird (*Molothrus ater*). This bird is a brood parasite—that is, it lays its eggs in the nests of other bird species and its hatchlings are raised by the host parents, to the detriment of their own young (see the opening of Chapter 53). Historically,

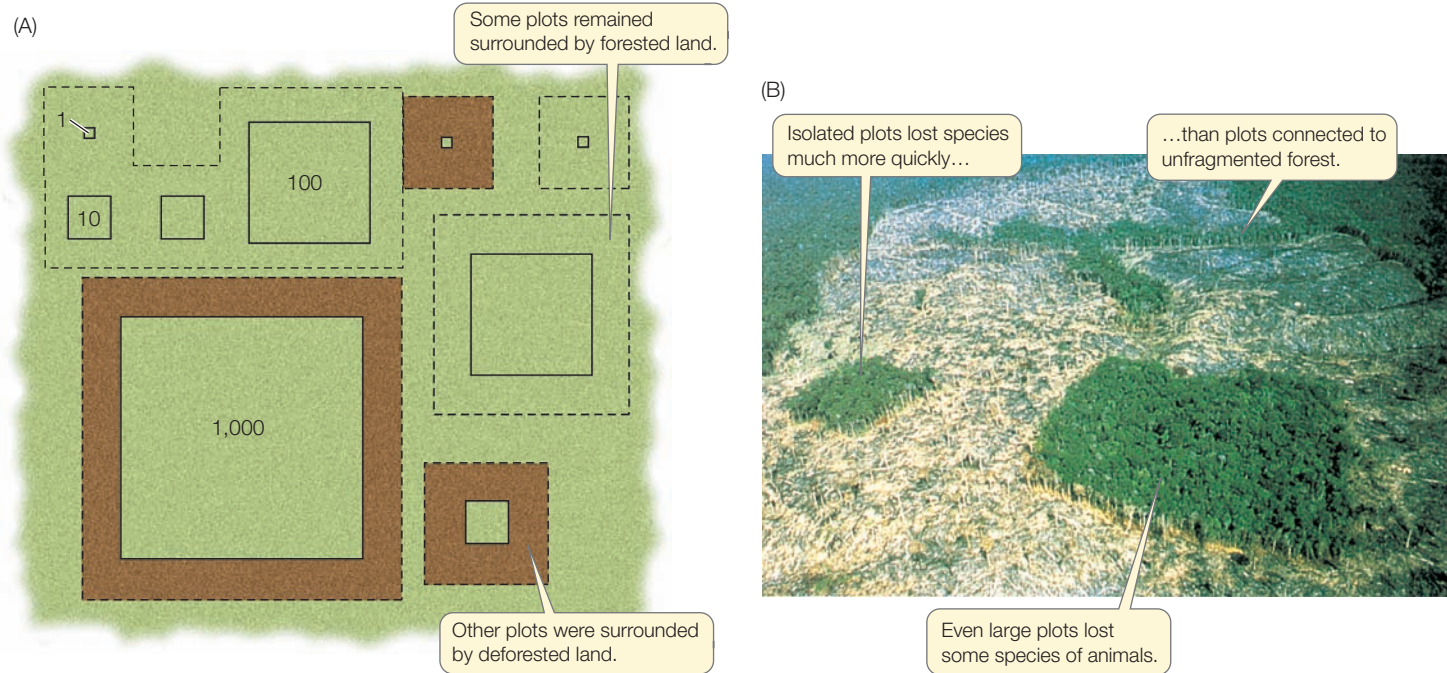

59.5 Edge Effects The smaller a patch of habitat, the greater the proportion of that patch that is influenced by conditions in the surrounding environment.

 **Go to Animated Tutorial 59.1**
Edge Effects
Life10e.com/at59.1

cowbirds followed bison and other grazing mammals, feeding on insects kicked up by the herds; thus their eggs were laid primarily in nests of grassland host species. Forest fragmentation, however, opened up new opportunities for the cowbirds, which can now lay their eggs in the nests of forest birds in forest edges. Fragmented forests, with relatively more edge than intact forests, thus favor the proliferation of cowbirds at the expense of forest species.

Because so many habitats have already undergone fragmentation by the time they are first investigated by ecologists, determining the effects of fragmentation on the original communities can be difficult. Timely surveys can provide some of this information. For example, a major research project was launched in 1979 in a tropical rainforest near Manaus, Brazil, that was slated for conversion to pasture. The landowners agreed to preserve forest plots of certain sizes and configurations laid out by biologists (**Figure 59.6A**). The biologists counted the species in the future “fragments” while they were still part of the continuous forest, then monitored these plots after the surrounding forest was cut (**Figure 59.6B**). Species soon began to disappear from isolated plots. The first species to be eliminated were monkeys that travel over large areas. Army ants and the birds that follow army ant swarms also disappeared quickly.

Species that are lost from small habitat fragments are unlikely to become reestablished there because dispersing individuals are unlikely to find the isolated fragments. As Section 55.5 pointed out, however, a species may persist in a small patch if it is connected to other patches by habitat corridors through which individuals can disperse. Among the experimental forest plots in Brazil, those that were completely isolated

59.6 Species Losses in Fragmented Brazilian Forest Biologists studied plots of tropical rainforest near Manaus, Brazil, before and after they were isolated by forest clearing. (A) The landowners agreed to preserve forest plots of certain sizes and configurations

according to a plan laid out by the biologists. (B) Some of the plots after clearing. The results of the study demonstrated that small, isolated habitat plots lost species more quickly than did larger plots of the same habitat.

lost species more rapidly than did those that were connected to unfragmented forest by corridors. Since the experiment began, some of the pastures that surrounded the experimental plots have been abandoned, and young forests now grow in them. Within 9 years of abandonment, army ants and some of the birds that follow them recolonized forest fragments connected to larger forest fragments by young forests that served as dispersal corridors. Other birds that forage in the forest canopy also reestablished themselves. Young forest is not a suitable permanent habitat for most of these species, but they can disperse through it to find more appropriate habitat.

Insight into the importance of corridors has led to new regional conservation initiatives, among the most notable of which is the Yellowstone to Yukon Conservation Initiative. This joint Canada–United States nonprofit organization has as its goal the sustainable preservation of the mountain ecosystem extending from Yellowstone National Park in the United States to Yukon, Canada. This stretch of land, the largest intact ecosystem of its kind on the planet, contains high-quality habitat for many of North America’s most imperiled animals, including grizzly bears, gray wolves, lynx, and native fishes. The initiative works with landowners to find sustainable ways of preserving high-quality, well-connected wildlife habitat in the region. Managing the entire region in this way will not only provide habitat for these species, but will also provide room for their populations to shift in response to global climate change.

Overexploitation has driven many species to extinction

Overexploitation was once the most important cause of species extinctions. Although habitat loss now presents a greater threat to more species, many species are still threatened by

overexploitation. Particularly at risk are species with life history traits that are linked to slow population growth (see Section 55.3), which make recovery from losses less likely. Elephants and rhinoceroses, for example, are slow to reach reproductive maturity and produce relatively few offspring over the course of their lives; they are at risk in much of Africa and Asia because poachers kill elephants for their valuable ivory tusks and rhinoceroses for their horns (primarily based on a long-prevalent but false belief that imbibing drinks made with powdered rhinoceros horn boosts a man’s sexual potency).

The principal threat to the continued survival of tigers, whose numbers have declined by more 90 percent since 1900 (**Figure 59.7A**), is the use of their body parts in traditional medicine—bones to treat rheumatism, eyes to cure epilepsy, and penises to enhance virility. In 2009 a bowl of tiger penis soup could be obtained for \$300 in Taiwan. There is some hope that the availability of inexpensive drugs for treating erectile dysfunction will reduce the incidence of poaching of these and other endangered species, but hopes are dim for eliminating poaching altogether in Asia and Africa. Demand for traditional animal-based medicines remains high, and animal aphrodisiacs provide an economic boon for impoverished hunters and a status symbol for the rich.

Massive international trade in exotic pets and aquarium fishes, ornamental plants, and tropical forest hardwoods has decimated many species. The Banggai cardinalfish (*Pterapogon kauderni*; **Figure 59.7B**) is on the brink of extinction entirely because of the pet trade; almost a million of these critically endangered fish are hauled out of the waters annually near Sulawesi, Indonesia, to satisfy the demand from saltwater aquarium enthusiasts.

(A)

(B) *Pterapogon kauderni*

59.7 Endangered by Exploitation (A) Skins confiscated at the China–Myanmar border illustrate the extent of poaching of endangered tigers (*Panthera tigris*). Beyond the value of their pelts, tiger bones and other body parts are highly prized in Asian traditional medicine. (B) The international pet trade has brought the Banggai cardinalfish to the brink of extinction. Each year almost a million of these critically endangered fish are hauled out of Indonesian coral reef waters to satisfy the demand from saltwater aquarium enthusiasts.

Burgeoning human populations in need of food are also placing unprecedented pressure on species harvested from the wild. Humans have captured wild fish for food for at least 40,000 years, but in recent centuries innovations in technology and increasing demand have led to removal of fish from wild populations at rates that far exceed the capacity of the remaining individuals to reproduce. An estimated 25 percent of the world’s wild fisheries are currently at risk of overexploitation and collapse. Deep-sea fish that are slow to mature and produce relatively few offspring, such as the orange roughy (*Hoplostethus atlanticus*), are especially sensitive to overexploitation.

Invasive predators, competitors, and pathogens threaten many species

As people travel, they deliberately or inadvertently move species to regions outside their original ranges. Some of these non-native species become **invasive**—that is, they reproduce rapidly, spread widely, and have negative effects on the native

Boiga irregularis

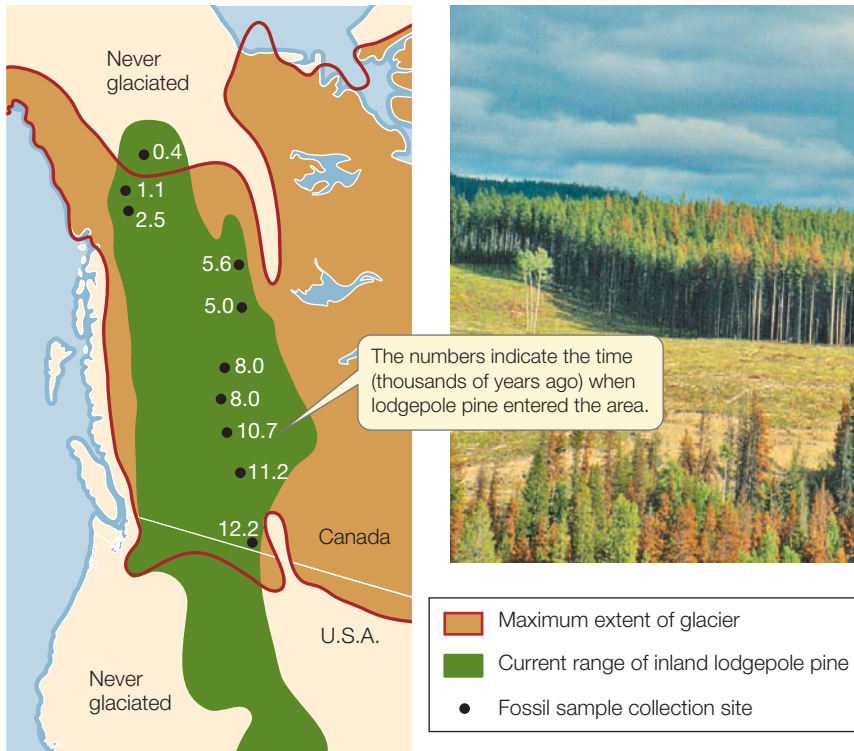

59.8 An Agent of Extinction Since it was accidentally introduced onto the tiny Pacific island of Guam, the brown tree snake (*Boiga irregularis*) has eaten 15 species of land birds to extinction.

species of the region. As we saw in Section 55.4, species that are introduced into a region where their natural enemies are absent may reach very high population densities. Moreover, the native species in an invader’s new range may not have evolved defenses against these new antagonists and competitors.

Invasive species are spread in several ways. Marine organisms have been spread throughout the oceans by ballast water, taken on by ships at the port of departure and discharged at the destination port along with its content of surviving animals and plants. The notorious zebra mussel (*Dreissena polymorpha*; see Figure 55.10) is thought to have arrived in North America in this way. The brown tree snake (*Boiga irregularis*; **Figure 59.8**) arrived on Guam in air cargo shortly after World War II. Until then, the only snake on Guam was a tiny insect-eating species. The number of *B. irregularis* on Guam remained low for some 20 years, but in the 1960s the species began to multiply and today can be found at densities up to 5,000 individuals per square kilometer. The snake has exterminated 15 species of land birds, including 3 found only on Guam.

Over the past 400 years, Europeans colonizing new continents have deliberately introduced plants and animals to their new homes in an effort to reconstruct their familiar surroundings. Many of these introductions have had disastrous effects on native flora and fauna. In Australia the introduction of European rabbits and foxes for sport hunting and of dogs and cats as pets has led to the extermination of nearly half the small- to medium-sized native marsupials over the last 100 years. Some species have been introduced deliberately to control other invasive species, and then have themselves caused even greater problems. One such example is the cane toad (*Bufo marinus*), introduced into Australia to control sugarcane pests (see Figure 55.15).

It can be difficult for people to imagine that plants that are desirable and attractive in their place of origin can “go rogue” when they escape from cultivation in a new region. Some of today’s most noxious weeds were deliberately transported and

59.9 Some Species Have Expanded Their Range

Lodgepole pines (*Pinus contorta*) expanded their range northward as the continental glaciers that covered North America during the Pleistocene retreated.

planted in new places for their beauty, fragrance, or culinary value. Once established in their new environments, however, these invasive plants have had profoundly negative effects. While native plants must devote considerable energy and resources to defending themselves against native herbivores, invasive plants are less prone to attack, in part because their natural enemies have been left behind in their original range. Therefore invasive plants can devote more resources to growth and reproduction and fewer to producing defensive secondary compounds. The majority of plants considered by U.S. farmers to be weeds are non-native, and controlling them, primarily with chemical herbicides, costs billions of dollars every year.

Introduced pathogens have also wreaked havoc among native species, as exemplified by the effects of avian malaria in the Hawaiian Islands. Before the arrival of Europeans, no mosquitoes existed in the islands. The first mosquito species was found there in 1827, and over the next century several others followed. At the start of the twentieth century, the microbial pathogen that causes avian malaria arrived, most likely carried by imported caged birds. Not having been exposed to malaria over the course of their evolutionary history, Hawaii's many endemic bird species were exceptionally vulnerable to infection. Today nearly all species living below 1,500 meters elevation (the current upper limit of the range of the mosquito vectors) have been eliminated, mostly by avian malaria. Species living at higher elevations have fared better, but the range of the mosquitoes appears to be expanding upward as the climate warms, placing the surviving endemic species at risk.

Rapid climate change can cause species extinctions

As we saw in Section 58.3, human-generated emissions of greenhouse gases are hastening global climate warming, and that warming is likely to become an increasingly important

cause of extinctions. Across North America, for example, average annual temperatures are predicted to increase anywhere from 2°C to 5°C by the end of the twenty-first century. If the climate warms to that extent, the average temperature found at any given location in North America today will shift 500 to 800 kilometers to the north. Those species that cannot adapt to the warmer climate will have to shift their geographic ranges by that distance within less than a century if they are to persist. Some biomes, such as alpine tundra, could disappear entirely as temperate forests expand up mountain slopes.

Efforts to control or reverse global warming present a challenge to people worldwide. Conservation biologists can contribute to discussions about how to respond to climate change by predicting how it may affect organisms and looking for ways to mitigate those effects. Their research activities include analyses of past climate changes and studies of sites currently undergoing rapid climate change. It would be helpful to know, for example, how rapidly species responded to the end of the most recent ice age, about 10,000 years ago. Which species did and did not keep pace with the warming climate? How much, and in what ways, do past ecological communities differ from those of today as a result of differences in the rates at which species' ranges shifted?

Species that can disperse easily, such as birds and insects that can fly considerable distances, may be able to shift their ranges as rapidly as the climate changes, provided they can find appropriate habitats. However, the ranges of other species are likely to shift more slowly. For example, after the glaciers retreated in North America about 8,000 years ago, the ranges of some pine trees, which have lightweight seeds that can be carried great distances by wind, expanded northward, so that today they grow as far north as the current climate permits (Figure 59.9). Native earthworms, on the other hand, fared

less well—the glaciers may well have eliminated all earthworm species in Canada, and they have not been replaced by other North American species, which have moved their ranges northward only slowly. (Many of the earthworms found in the United States today are non-native species accidentally introduced from elsewhere.)

If Earth's surface warms as predicted, entirely new climates will develop, especially at low elevations in the tropics, where a warming of even 2°C would result in conditions warmer than those found anywhere in the humid tropics today. Adaptation to those climates may prove difficult even for many tropical organisms. Since the mid-1980s, the average minimum nightly temperature at La Selva Biological Station, in the Caribbean lowlands of Costa Rica, has increased from about 20°C to 22°C. On warmer nights, trees use more of their energy reserves to maintain themselves. As a result, even this small rise in temperature has reduced the average growth rates of six different tree species by about 20 percent.

RECAP 59.3

Several human activities threaten the persistence of species, including habitat degradation, fragmentation, and destruction; overexploitation; introductions of invasive species; and activities that cause rapid climate change.

- Describe three ways in which habitat loss is occurring today. [See p. 1233](#)
- Why are rates of species loss high in small habitat patches? [See pp. 1233–1234 and Figures 59.5 and 59.6](#)
- How can dispersal ability and climate change interact to affect the probability of extinction? [See pp. 1236–1237](#)

Demonstrating that species are endangered is an empty exercise if we cannot implement a plan of action to save them. In the next section we will consider some of the positive steps that are being taken to protect biodiversity.

59.4

What Strategies Are Used to Protect Biodiversity?

Conservation biologists use scientific theory, empirical data, and tools from a variety of disciplines to help protect endangered and threatened species and ecosystems. They identify the factors that present risks to species and use that information to devise action plans. Implementing those plans, however, often requires the cooperation of many different groups of people, so conservation biologists also work with landowners, politicians, lawyers, environmental activists, and the general public. It is thus very useful to examine the actions that conservation biologists and policy makers take to protect biodiversity in order to determine which approaches have been most successful and to understand what aspects have contributed to their success.

Protected areas preserve habitat and prevent overexploitation

The establishment of **protected areas**, in which habitat alteration and exploitation are restricted or prohibited, is an

important component of efforts to conserve biological diversity. Protected areas allow populations to maintain themselves in the preserved habitat and may also serve as nurseries from which individuals can disperse into exploited areas, replenishing populations that might otherwise become extinct.

Deciding which areas to protect is a challenging enterprise. Two robust criteria are species richness (the total number of species living in an area; see Section 57.3) and **endemism** (the number of species in an area that are found nowhere else—a measure of its uniqueness). Using these two criteria, biologists have identified regions of unusual richness and endemism, which they have labeled **biodiversity hotspots** (Figure 59.10). These hotspots occupy slightly less than 16 percent of Earth's land surface, but they are home to approximately 77 percent of its terrestrial vertebrate species. Most of these hotspots are also areas of high human population density, which means habitat loss is ongoing and often rapid. Developing a conservation strategy for any of these regions requires not only a detailed analysis of the distributions of species and the locations of special habitat resources (such as caves, freshwater springs, or migratory stopover areas for birds), but also an analysis of factors that threaten and factors that support biodiversity in the region.

In 2010, in an effort to pinpoint sites with threatened species that are found nowhere else, conservation biologists identified 587 “centers of imminent extinction.” These sites are concentrated in tropical forests, on islands, and in mountainous regions (Figure 59.11). Only about half the sites are even partially protected by law, and most of them are surrounded by land that is undergoing rapid development. Unless protective actions are taken soon, species extinctions at these sites are inevitable. Identifying biodiversity hotspots and centers of imminent extinction has been helpful in prioritizing conservation efforts worldwide, encouraging international cooperation, and raising public awareness of critical threats to species persistence.

Degraded ecosystems can be restored

When a species is endangered as a consequence of habitat degradation rather than outright habitat loss, protecting the species may require restoring the habitat to a more natural state. Many degraded ecosystems recover only slowly, if at all, without human assistance. Practitioners of **restoration ecology** are developing methods aimed at just such habitat reconstitution.

Because the soil that supports them is so rich, grasslands all over the world have been converted to agriculture. By the middle of the twentieth century, for example, most North American prairies had been converted to cropland or were heavily grazed by domestic livestock. The herds of large mammals that roamed the prairies when European settlers arrived have been reduced to tiny remnant populations confined to small areas. Most of these populations are too small to maintain their genetic diversity or to function in their original ecological roles. The species *have* survived, however, so opportunities exist to reintroduce them if their habitat can be restored.

A major prairie restoration project is underway in northeastern Montana. When Lewis and Clark mapped this region 200

(A) Tropical rainforest hotspots

(B) Hotspots in other biomes

59.10 Hotspots of Biodiversity

(A) Almost half of the world's terrestrial biodiversity hotspots are regions of tropical rainforest habitat. There are only three remaining areas of extensive unbroken rainforest (Amazonia, the Congo Basin of Africa, and the island of New Guinea; see Figure 59.4). (B) Eighteen additional hotspots represent non-rainforest ecosystems.

years ago, they saw large herds of bison, elk, deer, and pronghorn as well as abundant populations of their predators. The goal of the restoration project, which is run by the World Wildlife Fund and the American Prairie Foundation in cooperation with public land managers and several other private conservation organizations, is to restore the native prairie and its fauna in a 15,000-km² area near the Missouri River (**Figure 59.12**).

This ambitious project is feasible for three reasons. First, the private land in the area is owned by a small number of ranchers, each of whom owns extensive grazing leases on public lands administered by either U.S. federal agencies or the State of Montana. Second, most of the land has never been plowed,

59.11 Centers of Imminent Extinction Areas shown in yellow include many of the world's 587 "centers of imminent extinction" (as designated in 2010 by the Alliance for Zero Extinction, a coalition of more than 80 conservation groups). Although there are scattered centers in other regions, the areas highlighted here harbor an estimated 1,000 endemic species (species found nowhere else) known to be at high risk of extinction.

"Centers of imminent extinction" are concentrated in tropical forests, islands, and mountains. Compare to Figure 59.10 and the satellite map in Figure 59.4.

(A)

59.12 Restoring a North American Prairie (A) A major prairie restoration project (yellow area) is under way north of the Missouri River in the state of Montana. (B) Native prairie dogs maintain the vegetation by digging extensive burrows and clipping plants. (C) The first bison were reintroduced to the area in 2005.

(B) *Cynomys ludovicianus*(C) *Bison bison*

so native vegetation may recover rapidly when grazing pressures are reduced. Third, the area's human population is decreasing. Ranchers are aging, and their children are abandoning the hard work and uncertain profits of ranching for careers in urban settings. Once a free-ranging herd of several thousand bison and large numbers of elk—along with their predators (wolves)—has been established, nature-minded tourists are expected to flock to the area to view the wildlife spectacle. Over the long term, the restored ecosystem should deliver major economic benefits to the region.

In the United States, the sense that humans are capable of creating functioning ecosystems to replace those lost to development underlies policies that allow developers to destroy habitats. Destruction of wetlands, in particular, is often permitted because developers assert that those ecosystems can be replaced. However, creating new wetlands requires detailed ecological knowledge that generally surpasses what is currently available.

In southern California, where 90 percent of the coastal wetlands have been destroyed, wetland restoration is a high priority. Species have been lost from degraded coastal wetlands, so restoration requires species introductions. Early attempts at restoration, in which one or two common wetland species were introduced, did not succeed; other wetland-associated species failed to recolonize the “rehabilitated” wetlands. To understand why, conservation biologists established a large field experiment at the Tijuana Estuary near San Diego (**Figure 59.13**). Here they found that experimental plots planted with species-rich mixtures were covered with vegetation faster, developed a complex vegetation structure (which is important to insects and birds) more rapidly, and accumulated nitrogen (required for plant growth) faster than did species-poor plots (**Figure 59.14**). This outcome represents a practical demonstration

of the relationship between community stability and species richness (see Section 57.5).

Disturbance patterns sometimes need to be restored

Many species depend on particular patterns of disturbance—such as fires or windstorms—to maintain their populations (see Section 57.4). Recognition of the need for periodic disturbance to maintain healthy ecosystems is a relatively new dimension

59.13 A Wetlands Laboratory The Tijuana Estuary near San Diego is a shallow-water wetland habitat. Experiments at this natural research reserve have advanced efforts to restore this valuable ecosystem.

INVESTIGATING LIFE

59.14 Species Richness Can Enhance Wetland Restoration

In a large-scale experiment in the Tijuana Estuary, John Callaway and other ecologists from the Southern California Wetlands Recovery Project compared different methods for restoring

shallow-water wetlands. They found that several measures of ecosystem function improved more rapidly in species-rich than in species-poor plantings.^a

HYPOTHESIS Faster progress toward restoring a shallow-water wetland community to its original condition will be made by planting mixtures of species than by planting a single species.

Method

1. In an area of wetland denuded of vegetation, mark off replicate experimental plots, all of the same size.
2. Choose 8 native species typical of the region. Plant some plots with 1 of the 8 species by itself, others with different subsets of 3 species, and others with different subsets of 6 species. Plant the same total number of seedlings in each plot. Leave control plots unplanted.
3. Measure the percent ground cover, number of canopy layers, and soil nitrogen levels at 6-month intervals over the next 18 months.

Results

In the plots with higher species richness, more of the ground was covered by plants, the vegetation structure was more complex, and more nitrogen accumulated in the soil.

CONCLUSION Planting a rich mixture of species leads to more rapid restoration of shallow-water wetlands.

Go to **BioPortal** for discussion and relevant links for all **INVESTIGATING LIFE** figures.

of conservation biology. For example, although many plant species require periodic fires for successful establishment and survival, for many years the official policy of the U.S. Forest Service, symbolized by the iconic mascot Smokey Bear, was to suppress all forest fires. Today, however, controlled burning is common, particularly in western North America. In order to use fire as an ecosystem management tool, it is important to know the historical pattern of fires in an area, which can be determined in part by studies of the annual growth rings and fire scars of trees (**Figure 59.15**). A schedule of controlled burning that recreates the historical pattern can reduce forest floor litter, avoiding a buildup of fuel that can lead to intense, tree-killing canopy fires.

Ending trade is crucial to saving some species

Most endangered species cannot survive any further reductions in their breeding populations, so it is important to prevent their exploitation. The legal mechanism for prohibiting trade in these species or their products is an international agreement called the Convention on International Trade in Endangered Species (CITES). Most nations of the world are members of CITES. CITES rules currently prohibit international trade in items such as whale meat, rhinoceros horns, and many species of parrots, orchids, and others.

The recent history of elephant poaching and trade in ivory illustrates how complex preventing exploitation of endangered species can be. CITES instituted a ban on international trade in African elephant ivory in 1989, but demand for ivory remains strong, especially in Asia. As a result, poaching of elephants continues in the forests of central and East Africa, where the animals are threatened. However, some countries, including Malawi and Zambia, have so many elephants that government officials kill them to control populations and prevent the animals from damaging crops. These countries would like to sell the ivory from culled elephants to fund conservation efforts, but other countries are worried that if restrictions are relaxed, poaching will escalate everywhere.

Control of ivory trade might be possible if scientists could determine where the ivory comes from. Conservation biologist Samuel Wasser and his colleagues identified 16 DNA markers from elephant feces collected by park rangers in Malawi and Zambia. The source of an elephant tusk could then be determined by matching DNA extracted from the ivory with the geographically based frequencies of the 16 DNA markers in the dung samples. Such safeguards were partially responsible for the controversial decision to sanction sales of ivory from Namibia, Botswana, Zimbabwe, and South Africa in 2008, the first such sales in close to a decade. More than 100 tons of

59.15 A Natural Disturbance Pattern As revealed by scars (arrows) in the growth rings of this ponderosa pine (*Pinus ponderosa*), low-intensity, nonlethal ground fires were frequent in the pine forests of the southwestern United States prior to fire suppression.

elephant tusks—the equivalent of 20,000 dead elephants—were auctioned off to authorized buyers from China and Japan, for use primarily in folk medicine. This legal sale generated some \$15 million for elephant conservation efforts.

Although the 2008 sales were monitored by CITES, concerns remain that the flood of legal ivory will be intermingled with poached ivory. One promising development in curbing illegal sales was the decision by eBay, the international internet marketplace, to ban sales of ivory on its platform as of January 2009. An independent investigation by the International Fund for Animal Welfare stated that two-thirds of online sales of protected wildlife products take place on eBay, so conservationists hope eBay's actions will be effective in drying up markets. Notwithstanding such efforts, illegal poaching, smuggling, and trafficking of ivory have all increased, and representatives from 175 countries attending the 2010 meeting of CITES in Qatar voted to ban sales of stockpiled elephant ivory for at least 3 years.

Species invasions must be controlled or prevented

The best way to reduce the damage caused by invasive species is to prevent their introduction in the first place. Given the tremendous volume of global trade, it might seem impossible to curtail their spread, but some promising strategies do exist. For example, transoceanic transport of invasive species in ballast water (responsible for the devastation caused by the invasive

zebra mussel; see Figure 55.10) could be largely eliminated by the simple procedure of deoxygenating ballast water before it is pumped out. This practice not only kills most organisms in the water but also extends the life of ballast tanks—an economic benefit to shippers.

In 1996 the U.S. Congress responded to concerns about ballast water with legislative action. After years of wrangling, in 2012 the U.S. Coast Guard amended its regulations on managing ballast water to set standards for “the allowable concentration of living organisms in ballast water discharged from ships in waters of the United States.” The Coast Guard relied on scientific reports issued by the National Academy of Sciences and the U.S. Environmental Protection Agency Science Advisory Board to specify the most stringent discharge standards achievable with current technology. Despite the adoption of these strict standards for protecting U.S. waterways, the challenge of achieving global uniformity remains. The transport of invasive aquatic organisms in ballast water is an international problem whose potential solutions continue to run up against political and economic barriers.

Regulating the importation and sale of non-native plant species has been more successful in reducing deliberate introductions. In 2002, members of the American horticulture industry crafted a voluntary code of conduct for their profession, stating that the invasive potential of a plant should be assessed prior to its introduction and marketing. Horticulturists were encouraged to work with biologists to determine which species are currently invasive, or are likely to become so, and to identify suitable alternative species.

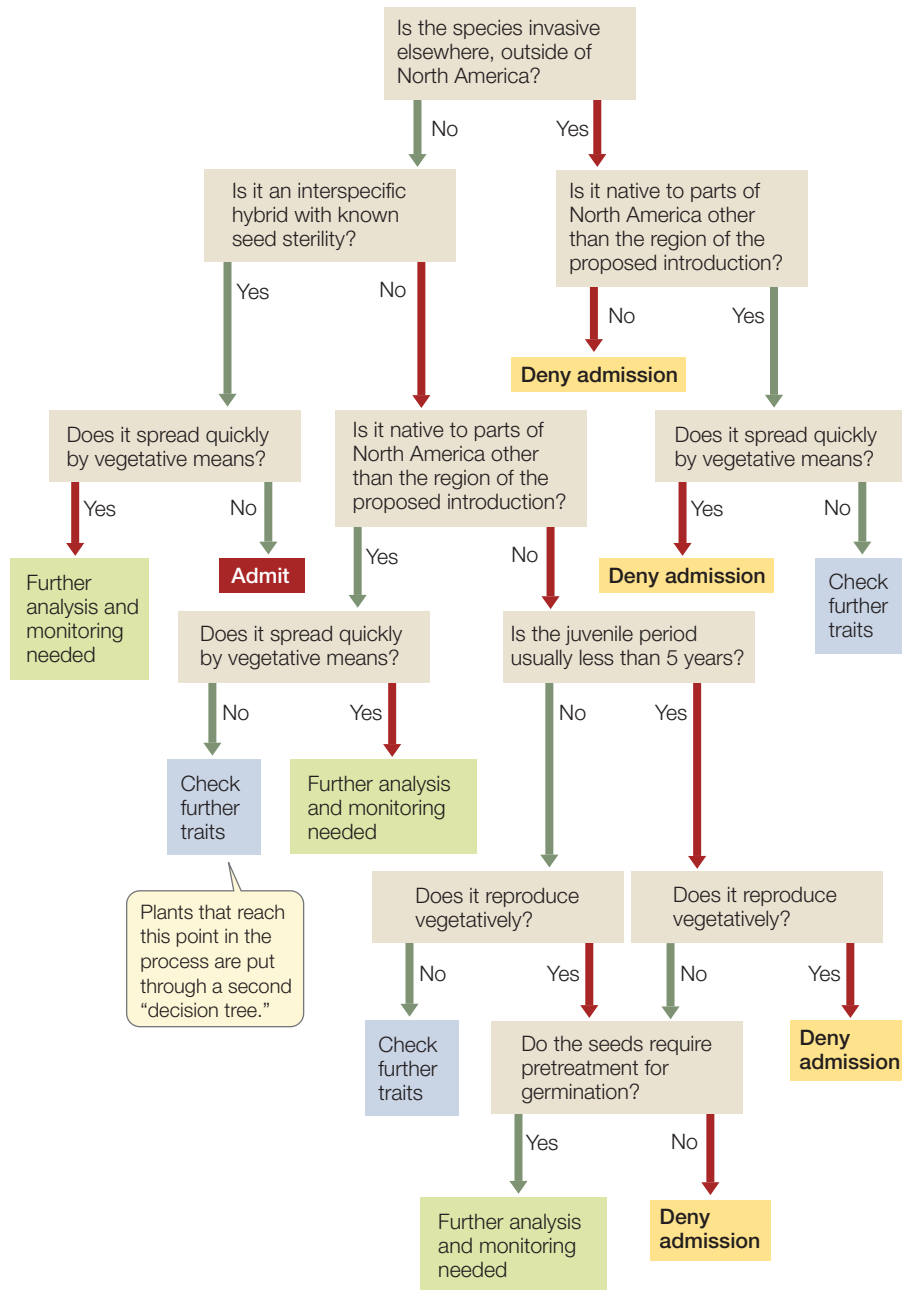

Conservation biologists have developed a “decision tree” based on the traits that characterize plant species that have become invasive (Figure 59.16). The tree is used to help horticulturists and regulators determine whether a non-native plant species should be allowed into North America. Although the protocols stipulated by this decision tree cannot eliminate all detrimental introductions, if followed conscientiously they can greatly reduce the risk of such events.

Biodiversity has economic value

Many studies have demonstrated the market value of protecting biodiversity. Markets already exist for many products of biodiversity; to cite just one example, sales of pharmaceuticals derived from plants worldwide amount to more than \$30 billion annually. Thus the argument for conservation is compelling not only from an ecological or ethical perspective but also from an economic perspective. The interdisciplinary field of **ecological economics** provides tools for assessing the economic value of biodiversity.

Crucial to ecological economics is recognizing and determining the value of services that thriving ecosystems provide to human society (see Section 58.4). These services depend on biodiversity, but it is difficult to assess their value in monetary terms. Ecosystem services that depend on the maintenance of biodiversity include:

- *Provisioning services*, including the availability of food and water for human consumption.

The following three examples illustrate how biodiversity can offer a range of benefits to human populations that more than justify investing in conservation.

WILD DOGS AND ECOTOURISM **Ecotourism**—environmentally responsible travel to natural areas, the proceeds of which support conservation efforts and the economic well-being of the local communities—is a major source of income for many developing nations. For example, tourists visiting Africa often express interest in seeing wild dogs (*Lycaon pictus*; **Figure 59.17**). However, diseases such as rabies and canine distemper, along with habitat loss, roadkills, deliberate extermination due to a perceived threat to livestock, and many other factors have decimated wild dog populations, making this the second most endangered carnivore in Africa. (Another canid, the Ethiopian wolf *Canis simensis* is first.) South Africa is home to about 400 of Africa's remaining 5,000 dogs, most of which live in Kruger National Park. Their endangered status has piqued tourist interest in these charismatic animals; a survey of visitors to South Africa revealed that nearly three-fourths of them would be willing to pay an extra U.S. \$12 for the opportunity to see wild dogs. Conservation biologists are working with lodge owners and ranchers elsewhere in South Africa and in Kenya to encourage them to reestablish wild dogs in areas from which they have disappeared.

FYNBOS Studies by a group of economists, ecologists, and land managers have attempted to calculate the value of the economic benefits provided by the spectacularly species-rich fynbos community (described at the opening of Chapter 54) to the Western Cape Province of South Africa. More than two-thirds of the 8,500 plant species in the fynbos community are endemic, thriving despite summer droughts, nutrient-poor soils, and periodic fires. Some of the endemic plants, including proteas, are harvested for cut and dried flowers. An international market has developed for rooibos, a fynbos shrub used for herbal tea. Income also comes from hundreds of thousands of ecotourists who visit the region. The fynbos also provides recreational opportunities for local residents in urban areas nearby. Perhaps most importantly, however, the highland watershed in which fynbos thrive provides about two-thirds of the Western Cape's water supply.

In recent years several trees and shrubs from other continents have invaded the fynbos. Taller and faster-growing than the endemics, they displace the native vegetation, increasing the intensity and severity of fires. Moreover, because the

59.16 A "Decision Tree" This diagram sets criteria for evaluating proposed introductions of non-native plant species and helps regulators identify those species with the potential to become invasive.

- **Regulating services**, including the contributions of ecosystems to purification of water, flood control, pollination, and regulation of disease or pest outbreaks.
- **Supporting services**, including formation of soils and maintenance of nutrient cycles.
- **Cultural services**, including the provision of nonmaterial benefits such as recreational activities, psychological well-being, and spiritual enrichment (one example being the opportunities to fish for salmon and to watch eagles at Flathead Lake, described at the opening of this chapter).

59.17 A Sight for Ecotourists' Eyes Tourists visiting Africa to experience its wildlife often express a desire to see the endangered African wild dog (*Lycaon pictus*). Protecting such species (as seen here in South Africa's Mala Mala Game Reserve) can be in the economic interest of a region.

invaders transpire more water than the endemics, they could decrease stream flows to less than half of those from areas covered with native plants, drastically reducing the water supply for people in the region (Figure 59.18A).

We can get an idea of the economic value of fynbos biodiversity to the Western Cape Province by estimating the cost of maintaining or replacing the water supply services the fynbos provides. The South African government has launched an effort to maintain fynbos biodiversity by felling and digging out invasive trees and shrubs and by controlled fires (Figure 59.18B). This effort costs between \$140 and \$830 per hectare, depending on the densities of the invaders. Alternatively, the services provided by fynbos vegetation could be replaced, but at a much higher cost. A sewage purification plant that would deliver the same amount of water to the Western Cape Province as a well-managed watershed of 10,000 hectares would cost \$135 million to build and \$2.6 million per year to operate. Desalination of seawater would cost four times as much. Thus the available alternatives would deliver water at a cost somewhere between 1.8 and 6.7 times higher than the cost of maintaining natural vegetation in the watershed. Maintaining the fynbos is less expensive and more labor-intensive—thus generating more employment—than the technologically sophisticated methods that could substitute for the services it provides.

COFFEE AND POLLINATORS Taylor Ricketts and colleagues at Stanford University assessed the economic value of the pollination services provided by the bees that live in, and depend on, tropical forest patches adjacent to a coffee plantation in Costa Rica. They found that coffee production was highest at the sites that were closest to forest patches. They also hand-pollinated some coffee plants to show that the difference in production was a result of pollination services rather than

(B)

59.18 Biodiversity Maintains Ecosystem Functioning

(A) A computer simulation of change in stream flows over time from fynbos watersheds that have and have not been invaded by non-native trees and shrubs. (B) The Working for Water Programme has launched an effort to preserve the Western Cape Province's water supply by physically removing invasive species.

other environmental conditions. The investigators calculated that the value of pollination services to the plantation on which the experiments were carried out was about \$60,000 per year, more than the current conservation incentive payments offered to landowners to preserve forest patches.

Changes in human-dominated landscapes can help protect biodiversity

Establishing protected areas is an essential component of efforts to maintain biodiversity, but this action alone is insufficient to stem global biodiversity loss. The extensive landscapes in which people live and extract resources must also play important roles in biodiversity conservation. The good news is that, when carefully used, these lands can contribute much more to conservation than they currently do. The practice of using ecosystems for residences, resources, or recreation in ways that sustain their biodiversity is known as **reconciliation ecology**.

59.19 California Condors Make a Comeback

(A) California condors raised in captivity are fed by humans wearing hand puppets so that the birds will not imprint on their human captors and will be able to survive in the wild. (B) Numbered wing tags allow conservation biologists to identify and track released adult condors. The survival of North America's largest bird species depends on this captive propagation project.

(A)

(B) *Gymnogyps californianus*

Reconciliation ecology is based on the principle that most ecosystem services are provided locally, and that people are more motivated to work to protect their local interests than they are to work on national or global issues. The National Wildlife Federation has established a successful program in which people petition to have their backyards certified as wildlife-friendly. Criteria for certification include planting shrubs that provide food for birds and refraining from applying pesticides.

Even some industrial sites can support biodiversity. The Turkey Point power plant in southern Florida uses large amounts of water to cool its generating units. To cool the heated water before discharging it, the Florida Power & Light Company dug a system of 38 canals that covers 6,000 acres. These cooling canals are separated by low-lying berms that support a variety of native and non-native plants. Red mangroves grow along the edges of the canals. Today they support a thriving population of American crocodiles, a highly endangered species. Crocodiles living in the canals yield about 10 percent of all young crocodiles born in the United States. Having discovered the biodiversity value of its cooling system, the company employs biologists to monitor the crocodiles and works actively to ensure their continued reproductive success.

Captive breeding programs can maintain a few species

A few of the world's endangered species can be maintained in captivity while the external threats to their persistence are reduced or removed. However, captive propagation is only a temporary measure that buys time to deal with those threats. Zoos, aquariums, and botanical gardens do not have enough space to maintain adequate populations of more than a small fraction of Earth's endangered and threatened species. Nonetheless, captive propagation can play an important role by maintaining species during critical periods, providing a source

of individuals for reintroduction into the wild, and raising public awareness of threatened and endangered species.

The California condor, North America's largest bird, survives today only because of captive propagation (**Figure 59.19**). Two centuries ago, condors ranged from British Columbia to northern Mexico, but by 1978 the wild population was plunging toward extinction. Many of the birds, which are scavengers, had died from ingesting animal carcasses containing lead shot or bullets. To save the condor from certain extinction, biologists captured all the remaining condors—only 22 individuals—and initiated a captive breeding program in 1983.

The first captive-bred birds were released in the mountains north of Los Angeles in 1992. Since that time, there have also been releases in northern Arizona and Baja California. Today captive-bred birds use the same roosting sites, bathing pools, and mountain ridges that their wild-born predecessors did. In 2003 a wild-born chick fledged in the wild for the first time in more than two decades. By 2012 the number of condors living in the wild had reached 226, with another 179 living in captivity.

Most of the major threats to condor survival, including power lines, pesticides, and museum collectors, have been mitigated. Lead poisoning is still a problem, but as of July 1, 2008, under the Ridley–Tree Condor Preservation Act, California hunters are required to use non-lead bullets when hunting within the condor's range. Passage of this legislation marks a change in public attitudes from the days when cattle ranchers, in the mistaken belief that the condors killed livestock, vociferously opposed their reintroduction into the wild.

Earth is not a ship, a spaceship, or an airplane

Biologists often use metaphors to convey complex concepts, and ecologists in particular are fond of them. To convey the notion that human activities may be overwhelming the capacity of Earth's ecosystems to accommodate them, Herman Daly in 1966 introduced the metaphor of the Plimsoll line.

Since the nineteenth century, the Plimsoll line, or load line, has been painted on the side of ships that travel in international waters. If the Plimsoll line of a fully loaded ship anchored in port sinks below the water, there is a significant risk that, once at sea, the ship will capsize and the crew and cargo will be lost. Another ecological metaphor (also introduced in 1966, by Kenneth Boulding) is the concept of Spaceship Earth, which views humans as passengers on a planetary spaceship with limited supplies who must learn how to reuse and recycle in a “cyclical ecological system.” And finally, in their 1985 book *Extinction*, Paul and Anne Ehrlich used an airplane metaphor to frame their “rivet hypothesis.” According to this metaphor, ecosystems, like well-constructed airplanes, have redundant design features that allow certain parts to fail without causing a catastrophic breakdown: “A dozen rivets, or a dozen species, might never be missed. On the other hand, a thirteenth rivet popped from a wing flap, or the extinction of a key species ... could lead to a serious accident.”

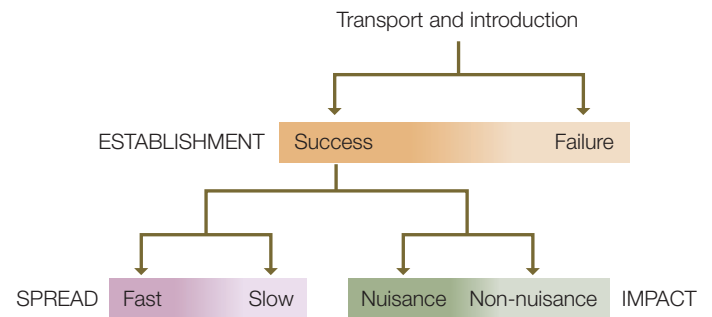

Even though they are remarkable human inventions, ships, spaceships, and airplanes are hopelessly inadequate to convey the enormous complexity of life. Moreover, relying on these metaphors creates a sense that we can rely on a few individuals—the captain or pilot and the “ship’s” crew—to ensure that the planet doesn’t capsize, run out of supplies, or crash. In fact, *every individual has a responsibility to understand how Earth provides essential resources and services and to recognize the effects that using those resources has on other living beings.*

Humans share Earth with a staggering diversity of organisms, and our continued existence depends on our interactions with them. We may be unique as a species, however, in that we have the intellectual capacity to recognize, quantify, and if need be, mitigate the effects of those interactions. Learning all we can about life on Earth is perhaps our best tool for improving the quality of our own existence on the planet for the long haul.

RECAP 59.4

To conserve biodiversity, it is necessary to set aside protected areas, restore ecosystems and natural disturbance patterns, restrict trade in endangered species and transport of invasive species, increase populations of endangered species, and otherwise recognize the benefits of maintaining functioning ecosystems.

- What are some of the priorities that conservation biologists consider when establishing protected areas? [See p. 1237 and Figures 59.10 and 59.11](#)
- What are some of the material and non-material ecosystem services that depend on maintaining biodiversity? [See pp. 1241 and 1241–1243](#)
- Explain the difference between restoration ecology and reconciliation ecology. [See pp. 1237 and 1243–1244](#)

59.20 Three Steps to Invasion Invasion by a non-native species can be modeled as a process consisting of three steps, each with an independent probability of success or failure. To be considered invasive, the species must become established in a new environment, it must spread rapidly, and it must have an impact on its new environment.

How can adverse impacts of species introductions be anticipated before lasting damage occurs?

ANSWER

Conservation biologists use a range of tools to assess the risks of deliberate species introductions. In some cases, sufficient information is available from past introductions to allow biologists to identify the specific life history traits that make a species likely to become invasive. These traits can be used with a decision tree (see Figure 59.16), to guide decision-making. Mathematical models can also be constructed and used to assess the risks of both accidental and deliberate introductions. In one such model designed to identify potential fish invaders of the Great Lakes, investigators recognized three distinct stages

of invasion: establishment, spread, and impact (**Figure 59.20**). They systematically compared the traits of fish species that had succeeded at each stage with those of species that had failed at that stage. The characteristics they used were minimum temperature threshold, breadth of diet, and relative growth. By identifying the characteristics of the successful versus failed invaders, investigators were then able to recreate the invasion process and predict with 94 percent accuracy the fish species that succeeded or failed at each stage.

59.1 What Is Conservation Biology?

- **Conservation biology** is an applied scientific discipline devoted to protecting and managing biodiversity.
- Conservation biologists recognize that an understanding of the evolutionary processes that generate biodiversity is essential to protecting it. They also understand that ecosystems are dynamic, and that humans are part of those ecosystems.
- Species extinctions have always occurred, but they are currently occurring at a rate that rivals those of the five great mass extinctions in Earth's history.
- There are many compelling reasons for protecting biodiversity, including the maintenance of the species and ecosystems that provide humans with goods and services.

59.2 How Do Conservation Biologists Predict Changes in Biodiversity?

- Although our understanding of biodiversity is incomplete, biologists have identified many species that are threatened with extinction and have developed a classification system designed to aid in establishing policies for their protection. **See Figure 59.3**
- Biologists use the species–area relationship and the theory of island biogeography to estimate rates of extinction likely to be caused by habitat loss.
- To estimate a species' risk of extinction, statistical models take into account data on population sizes, demographic traits, genetic variation, physiology, and behavior.
- Rarity is not always a cause for concern, but species whose populations are shrinking rapidly are usually at risk of extinction.

59.3 What Human Activities Threaten Species Persistence?

- Habitat loss is the most important cause of species endangerment worldwide. As habitats become increasingly **fragmented**, more species are lost from those habitats. Small habitat patches can support only small populations and are adversely influenced by **edge effects**. **Review Figures 59.4, 59.5, 59.6, ANIMATED TUTORIAL 59.1**

- Overexploitation has historically been the most important cause of species extinctions, and it is still a major threat to biodiversity today.
- Some species introduced to regions outside their original range become **invasive**, causing extinctions of native species that have not evolved defenses against these new antagonists and competitors.
- Climate change is likely to become an increasingly important cause of extinctions for those species that cannot shift their ranges as rapidly as the climate warms. **Review Figure 59.9**

59.4 What Strategies Are Used to Protect Biodiversity?

- Establishing **protected areas** is crucial to conserving biodiversity. Protected areas are selected by taking into account species richness, **endemism**, and imminence of threats. **Review Figures 59.10, 59.11**
- **Restoration ecology** is an important conservation strategy because many degraded ecosystems will recover very slowly, if at all, without human assistance. **Review Figure 59.14**
- International trade in endangered species is controlled by regulations that most countries endorse.
- Conservation biologists work to determine which species are likely to become invasive and prevent their introduction to new areas. **Review Figure 59.16**
- Recognition of the economic value of biodiversity can help justify conservation efforts. **Review Figure 59.18**
- Even within landscapes where people live and extract resources, steps may be taken to protect biodiversity. This approach is known as **reconciliation ecology**.
- Captive breeding programs can maintain some endangered species for the short term while threats to their persistence in other natural habitats are reduced or removed.

CHAPTERREVIEW**REMEMBERING**

- Which of the following is not currently a major cause of species extinctions?
 - Habitat destruction
 - Meteorite impacts
 - Overexploitation
 - Introductions of non-native predators
 - Introductions of non-native pathogens
- Species extinctions matter to human society because
 - many important medications contain or are based on a plant product.
 - people derive aesthetic pleasure from interacting with other organisms.
 - causing species extinctions raises serious ethical issues.
 - biodiversity helps maintain valuable ecosystem services.
 - All of the above
- As a habitat patch gets smaller, it
 - cannot support populations of species that require large areas.
 - supports only small populations of many species.
 - is influenced to an increasing degree by edge effects.
 - is invaded by species from surrounding habitats.
 - All of the above

4. Global warming is a concern because
 - a. the rate of change in climate is projected to be faster than the rate at which many species can shift their ranges.
 - b. it is already too hot in the tropics.
 - c. climates have been so stable for thousands of years that many species lack the ability to tolerate variable temperatures.
 - d. climate change will be especially harmful to rare species.
 - e. None of the above
5. Scientists can determine the historical frequency of fires in an area by
 - a. examining charcoal in sites of ancient villages.
 - b. measuring carbon in soils.
 - c. radioactively dating fallen tree trunks.
 - d. examining fire scars in growth rings of trees.
 - e. determining the age structure of forests.
6. Captive propagation is a useful conservation tool provided that
 - a. there is space in zoos, aquariums, and botanical gardens to preserve the species indefinitely.
 - b. genetic uniformity of captive populations can be maintained.
 - c. the threats that endangered the species are being alleviated so that captive-reared individuals can later be released back into the wild.
 - d. there are sufficient caretakers.
 - e. None of the above; captive propagation should never be used because it directs attention away from the need to protect species in their natural habitats.
7. A plant species is most likely to become invasive when introduced to a new area if it
 - a. grows tall.
 - b. has become invasive in other places where it has been introduced.
 - c. is closely related to species living in the area where it has been introduced.
 - d. has specialized dispersers of its seeds.
 - e. has a long life span.

UNDERSTANDING & APPLYING

8. Conservation biologists have debated extensively which is better: many small protected areas (which may contain more species) or a few large protected areas (which may be the only ones that can support populations of species that require large areas). What ecological processes should be evaluated in making judgments about the sizes and locations of protected areas? How can principles of island biogeography be applied in this context?
9. The desert bighorn sheep of the southwestern United States is endangered. Its major predator, the puma, is also of conservation concern in the region. Under what conditions, if any, would it be appropriate to suppress the population of one rare species to assist another rare species?

ANALYZING & EVALUATING

10. During World War I, doctors adopted a “triage” system for dealing with wounded soldiers. The wounded were divided into three categories: those almost certain to die no matter what was done to help them, those likely to recover even if not assisted, immediately, and those whose probability of survival would be greatly increased if they were given immediate medical attention. Limited medical resources were directed primarily at the third category. What are some implications of adopting a similar approach toward species preservation?
11. Utilitarian arguments dominate discussions about the importance of preserving biological richness. In your opinion, what role should ethical and moral arguments play?

Appendix A The Tree of Life

Phylogeny is the organizing principle of modern biological taxonomy. A guiding principle of modern phylogeny is monophyly. A monophyletic group is considered to be one that contains an ancestral lineage and all of its descendants. Any such group can be extracted from a phylogenetic tree with a single cut.

The tree shown here provides a guide to the relationships among the major groups of extant (living) organisms in the tree of life as we have presented them throughout this book. The position of the branching “splits” indicates the relative branching order of the lineages of life, but the time scale is not meant to be uniform. In addition, the groups appearing at the branch tips do not necessarily carry equal phylogenetic “weight.” For example, the ginkgo [75] is indeed at the apex of its lineage; this gymnosperm group consists of a single living species. In contrast, a phylogeny of the eudicots [83] could continue on from this point to fill many more trees the size of this one.

The glossary entries that follow are informal descriptions of some major features of the organisms described in Part Seven of this book. Each entry gives the group’s common name, followed by the formal scientific name of the group (in parentheses). Numbers in square brackets reference the location of the respective groups on the tree.

It is sometimes convenient to use an informal name to refer to a collection of organisms that are not monophyletic but nonetheless all share (or all lack) some common attribute. We call these “convenience terms”; such groups are indicated in these entries by quotation marks, and we do not give them formal scientific names. Examples include “prokaryotes,” “protists,” and “algae.” Note that these groups cannot be removed with a single cut; they represent a collection of distantly related groups that appear in different parts of the tree. We also use quotation marks here to designate two groups of fungi that are not believed to be monophyletic.

Go to BioPortal at yourBioPortal.com for an interactive version of this tree, with links to photos, distribution maps, species lists, and identification keys.

– A –

acorn worms (*Enteropneusta*) Benthic marine hemichordates [119] with an acorn-shaped proboscis, a short collar (neck), and a long trunk.

“algae” Convenience term encompassing various distantly related groups of aquatic, photosynthetic eukaryotes [4].

alveolates (*Alveolata*) [5] Unicellular eukaryotes with a layer of flattened vesicles (alveoli) supporting the plasma membrane. Major groups include the dinoflagellates [51], apicomplexans [50], and ciliates [49].

amborella (*Amborella*) [78] An understory shrub or small tree found only on the South Pacific island of New Caledonia. Thought to be the sister group of the remaining living angiosperms [15].

ambulacrarians (*Ambulacraria*) [29] The echinoderms [118] and hemichordates [119].

amniotes (*Amniota*) [36] Mammals, reptiles, and their extinct close relatives. Characterized by many adaptations to terrestrial life, including an amniotic egg (with a unique set of membranes—the amnion, chorion, and allantois), a water-repellant epidermis (with epidermal scales, hair, or feathers), and, in males, a penis that allows internal fertilization.

amoebozoans (*Amoebozoa*) [84] A group of eukaryotes [4] that use lobe-shaped pseudopods for locomotion and to engulf food. Major amoebozoan groups include the loboseans, plasmodial slime molds, and cellular slime molds.

amphibians (*Amphibia*) [128] Tetrapods [35] with glandular skin that lacks epidermal scales, feathers, or hair. Many amphibian species undergo a complete metamorphosis from an aquatic larval form to a terrestrial adult form, although direct development is also common. Major amphibian groups include frogs and toads (anurans), salamanders, and caecilians.

amphipods (*Amphipoda*) Small crustaceans [116] that are abundant in many marine and freshwater habitats. They are important herbivores, scavengers, and micropredators, and are an important food source for many aquatic organisms.

angiosperms (*Anthophyta* or *Magnoliophyta*) [15] The flowering plants. Major angiosperm groups include the monocots [82], eudicots [83], and magnoliids [81].

animals (*Animalia* or *Metazoa*) [19] Multicellular heterotrophic eukaryotes. The majority of animals are bilaterians [22]. Other groups of animals include the sponges

[20], ctenophores [95], placozoans [96], and cnidarians [97]. The closest living relatives of the animals are the choanoflagellates [91].

annelids (*Annelida*) [105] Segmented worms, including earthworms, leeches, and polychaetes. One of the major groups of lophotrochozoans [24].

anthozoans (*Anthozoa*) One of the major groups of cnidarians [97]. Includes the sea anemones, sea pens, and corals.

anurans (*Anura*) Comprising the frogs and toads, this is the largest group of living amphibians [128]. They are tail-less, with a shortened vertebral column and elongate hind legs modified for jumping. Many species have an aquatic larval form known as a tadpole.

apicomplexans (*Apicomplexa*) [50] Parasitic alveolates [5] characterized by the possession of an apical complex at some stage in the life cycle.

arachnids (*Arachnida*) Chelicerates [114] with a body divided into two parts: a cephalothorax that bears six pairs of appendages (four pairs of which are usually used as legs) and an abdomen that bears the genital opening. Familiar arachnids include spiders, scorpions, mites and ticks, and harvestmen.

arbuscular mycorrhizal fungi (*Glomeromycota*) [88] A group of fungi [17] that associate with plant roots in a close symbiotic relationship.

archaeans (*Archaea*) [3] Unicellular organisms lacking a nucleus and lacking peptidoglycan in the cell wall. Once grouped with the bacteria, archaeans possess distinctive membrane lipids.

archosaurs (*Archosauria*) [38] A group of reptiles [37] that includes dinosaurs and crocodilians [133]. Most dinosaur groups became extinct at the end of the Cretaceous; birds [132] are the only surviving dinosaurs.

arrow worms (*Chaetognatha*) [98] Small planktonic or benthic predatory marine worms with fins and a pair of hooked, prey-grasping spines on each side of the head.

arthropods (*Arthropoda*) The largest group of ecdysozoans [25]. Arthropods are characterized by a stiff exoskeleton, segmented bodies, and jointed appendages. Includes the chelicerates [114], myriapods [115], crustaceans [116], and hexapods (insects and their relatives) [117].

ascidians (*Ascidacea*) “Sea squirts”; the largest group of tunicates [121]. They are sessile (as adults), marine, saclike filter feeders.

– B –

bacteria (*Eubacteria*) [2] Unicellular organisms lacking a nucleus, possessing distinctive ribosomes and initiator tRNA, and generally containing peptidoglycan in the cell wall. Different bacterial groups are distinguished primarily on nucleotide sequence data.

barnacles (*Cirripedia*) Crustaceans [116] that undergo two metamorphoses—first from a feeding planktonic larva to a nonfeeding swimming larva, and then to a sessile adult that forms a “shell” composed of four to eight plates cemented to a hard substrate.

bilaterians (*Bilateria*) [22] Those animal groups characterized by bilateral symmetry and three distinct tissue types (endoderm, ectoderm, and mesoderm). Includes the protostomes [23] and deuterostomes [28].

birds (*Aves*) [132] Feathered, flying (or secondarily flightless) tetrapods [35].

bivalves (*Bivalvia*) Major mollusk [106] group; clams and mussels. Bivalves typically have two similar hinged shells that are each asymmetrical across the midline.

bony vertebrates (*Osteichthyes*) [33] Vertebrates [31] in which the skeleton is usually ossified to form bone. Includes the ray-finned fishes [125], coelacanths [126], lungfishes [127], and tetrapods [35].

brachiopods (*Brachiopoda*) [103] Lophotrochozoans [24] with two similar hinged shells that are each symmetrical across the midline. Superficially resemble bivalve mollusks, except for the shell symmetry.

brittle stars (*Ophiuroidea*) Echinoderms [118] with five long, whip-like arms radiating from a distinct central disk that contains the reproductive and digestive organs.

brown algae (*Phaeophyta*) [54] Multicellular, almost exclusively marine stramenopiles [6] generally containing the pigment fucoxanthin as well as chlorophylls *a* and *c* in their chloroplasts.

bryozoans (*Ectoprocta* or *Bryozoa*) [99] A group of marine and freshwater lophotrochozoans [24] that live in colonies attached to substrates; also known as ectoprocts or moss animals. They are the sister group of entoprocts.

– C –

caecilians (*Gymnophiona*) A group of burrowing or aquatic amphibians [128]. They are elongate, legless, with a short tail (or none at all), reduced eyes covered with skin or bone, and a pair of sensory tentacles on the head.

calcareous sponges (*Calcarea*) [94] Filter-feeding marine sponges with spicules composed of calcium carbonate.

cellular slime molds (*Dictyostelida*) Amoebozoans [84] in which individual amoebas aggregate under stress to form a multicellular pseudoplasmodium.

cephalochordates (*Cephalochordata*) [120] See lancelets.

cephalopods (*Cephalopoda*) Active, predatory mollusks [106] in which the molluscan foot has been modified into muscular hydrostatic arms or tentacles. Includes octopuses, squids, and nautiluses.

cercozoans (*Cercozoa*) [56] Unicellular eukaryotes [4] that feed by means of threadlike pseudopods. Group together with foraminiferans [57] and radiolarians [55] to comprise the rhizaria [7].

charophytes (*Charales*) [67] See stoneworts.

chelicerates (*Chelicerata*) [114] A major group of arthropods [26] with pointed appendages (cheliceræ) used to grasp food (as opposed to the chewing mandibles of most other arthropods). Includes the arachnids, horseshoe crabs, pycnogonids, and extinct sea scorpions.

chimaeras (*Holocephali*) A group of bottom-dwelling, marine, scaleless chondrichthyan fishes [124] with large, permanent, grinding tooth plates (rather than the replaceable teeth found in other chondrichthyans).

chitons (*Polyplacophora*) Flattened, slow-moving mollusks [106] with a dorsal protective calcareous covering made up of eight articulating plates.

chlamydias (*Chlamydiae*) [46] A group of very small Gram-negative bacteria; they live as intracellular parasites of other organisms.

chlorophytes (*Chlorophyta*) [65] The most abundant and diverse group of green algae, including freshwater, marine, and terrestrial forms; some are unicellular, others colonial, and still others multicellular. Chlorophytes use chlorophylls *a* and *c* in their photosynthesis.

choanoflagellates (*Choanozoa*) [91] Unicellular eukaryotes [4] with a single flagellum surrounded by a collar. Most are sessile, some are colonial. The closest living relatives of the animals [19].

chondrichthyans (*Chondrichthyes*) [124] One of the two main groups of jawed vertebrates [32]; includes sharks, rays, and chimaeras. They have cartilaginous skeletons and paired fins.

chordates (*Chordata*) [30] One of the two major groups of deuterostomes [28], characterized by the presence (at some point in development) of a notochord, a hollow dorsal nerve

cord, and a post-anal tail. Includes the lancelets [120], tunicates [121], and vertebrates [31].

“chytrids” [90] Convenience term used for a paraphyletic group of mostly aquatic, microscopic fungi [17] with flagellated gametes. Some exhibit alternation of generations.

ciliates (*Ciliophora*) [49] Alveolates [5] with numerous cilia and two types of nuclei (micro-nuclei and macronuclei).

clitellates (*Clitellata*) Annelids [105] with gonads contained in a swelling (called a clitellum) toward the head of the animal. Includes earthworms (oligochaetes) and leeches.

club fungi (*Basidiomycota*) [90] Fungi [17] that, if multicellular, bear the products of meiosis on club-shaped basidia and possess a long-lasting dikaryotic stage. Some are unicellular.

club mosses (*Lycopodiophyta*) [71] Vascular plants [12] characterized by microphylls. See lycophytes.

cnidarians (*Cnidaria*) [97] Aquatic, mostly marine eumetazoans [21] with specialized stinging organelles (nematocysts) used for prey capture and defense, and a blind gastrovascular cavity. The sister group of the bilaterians [22].

coelacanth (*Actinista*) [126] A group of marine lobe-limbed vertebrates [34] that was diverse from the Middle Devonian to the Cretaceous, but is now known from just two living species. The pectoral and anal fins are on fleshy stalks supported by skeletal elements, so they are also called lobe-finned fishes.

coleochaetophytes (*Coleochaetales*) [66] Multicellular green algae characterized by flattened growth form composed of thin-walled cells. Thought to be the sister-group to the stoneworts [67] plus land plants [11].

conifers (*Pinophyta* or *Coniferophyta*) [77] Cone-bearing, woody seed plants [13].

copepods (*Copepoda*) Small, abundant crustaceans [116] found in marine, freshwater, or wet terrestrial habitats. They have a single eye, long antennae, and a body shaped like a teardrop.

craniates (*Craniata*) Some biologist exclude the hagfishes [122] from the vertebrates [31], and use the term craniates to refer to the two groups combined.

crenarchaeotes (*Crenarchaeota*) [47] A major and diverse group of archaeans [3], defined on the basis of rRNA base sequences. Many are extremophiles (inhabit extreme environments), but the group may also be the most abundant archaeans in the marine environment.

crinoids (*Crinoidea*) Echinoderms [118] with a mouth surrounded by feeding arms, and a U-shaped gut with the mouth next to the anus. They attach to the substratum by a stalk or are free-swimming. Crinoids were abundant in the middle and late Paleozoic, but only a few hundred species have survived to the present. Includes the sea lilies and feather stars.

crocodilians (*Crocodylia*) [133] A group of large, predatory, aquatic archosaurs [38]. The closest living relatives of birds [132]. Includes alligators, caimans, crocodiles, and gharials.

crustaceans (*Crustacea*) [116] Major group of marine, freshwater, and terrestrial arthropods [26] with a head, thorax, and abdomen

(although the head and thorax may be fused), covered with a thick exoskeleton, and with two-part appendages. Crustaceans undergo metamorphosis from a nauplius larva. Includes decapods, isopods, krill, barnacles, amphipods, copepods, and ostracods.

ctenophores (*Ctenophora*) [95] Radially symmetrical, diploblastic marine animals [19], with a complete gut and eight rows of fused plates of cilia (called ctenes).

cyanobacteria (*Cyanobacteria*) [43] A group of unicellular, colonial, or filamentous bacteria that conduct photosynthesis using chlorophyll *a*.

cycads (*Cycadophyta*) [74] Palmlike gymnosperms with large, compound leaves.

cyclostomes (*Cyclostomata*) This term refers to the possibly monophyletic group of lampreys [123] and hagfishes [122]. Molecular data support this group, but morphological data suggest that lampreys are more closely related to jawed vertebrates [32] than to hagfishes.

- D -

decapods (*Decapoda*) A group of marine, freshwater, and semiterrestrial crustaceans [116] in which five of the eight pairs of thoracic appendages function as legs (the other three pairs, called maxillipeds, function as mouthparts). Includes crabs, lobsters, crayfishes, and shrimps.

demosponges (*Demospongiae*) [93] The largest of the three groups of sponges [20], accounting for 90 percent of all sponge species. Demosponges have spicules made of silica, spongin fiber (a protein), or both.

deuterostomes (*Deuterostomia*) [28] One of the two major groups of bilaterians [22], in which the mouth forms at the opposite end of the embryo from the blastopore in early development (contrast with protostomes). Includes the ambulacrarians [29] and chordates [30].

diatoms (*Bacillariophyta*) [53] Unicellular, photosynthetic stramenopiles [6] with glassy cell walls in two parts.

dikaryotic fungi (*Dikarya*) [18] A group of fungi [17] in which two genetically different haploid nuclei coexist and divide within the same hypha; includes club fungi [90] and sac fungi [89].

dinoflagellates (*Dinoflagellata*) [51] A group of alveolates [5] usually possessing two flagella, one in an equatorial groove and the other in a longitudinal groove; many are photosynthetic.

diplomonads (*Diplomonadida*) [58] A group of eukaryotes [4] lacking mitochondria; most have two nuclei, each with four associated flagella.

- E -

ecdysozoans (*Ecdysozoa*) [25] One of the two major groups of protostomes [23], characterized by periodic molting of their exoskeletons. Nematodes [111] and arthropods [26] are the largest ecdysozoan groups.

echinoderms (*Echinodermata*) [118] A major group of marine deuterostomes [28] with five-fold radial symmetry (at some stage of life) and an endoskeleton made of calcified plates and spines. Includes sea stars, crinoids, sea urchins, sea cucumbers, and brittle stars.

elasmobranchs (*Elasmobranchii*) The largest group of chondrichthyan fishes [124]. Includes sharks, skates, and rays. In contrast to the other group of living chondrichthyans (the chimaeras), they have replaceable teeth.

embryophytes See land plants [11].

entoprocts (*Entoprocta*) [99] A group of marine and freshwater lophotrochozoans [24] that live as single individuals or in colonies attached to substrates. They are the sister group of bryozoans, from which they differ in having both their mouth and anus inside the lophophore (the anus is outside the lophophore in bryozoans).

eudicots (*Eudicotyledones*) [83] A group of angiosperms [15] with pollen grains possessing three openings. Typically with two cotyledons, net-veined leaves, taproots, and floral organs typically in multiples of four or five.

euglenids (*Euglenida*) [61] Flagellate excavates characterized by a pellicle composed of spiraling strips of protein under the plasma membrane; the mitochondria have disk-shaped cristae. Some are photosynthetic.

eukaryotes (*Eukarya*) [4] Organisms made up of one or more complex cells in which the genetic material is contained in nuclei. Contrast with archaeans [3] and bacteria [2].

eumetazoans (*Eumetazoa*) [21] Those animals [19] characterized by body symmetry, a gut, a nervous system, specialized types of cell junctions, and well-organized tissues in distinct cell layers (although there have been secondary losses of some or most of these characteristics in a few eumetazoan lineages).

euphyllophytes (*Euphyllophyta*) The group of vascular plants [12] that is sister to the lycophytes [71] and which includes all plants with megaphylls.

euryarchaeotes (*Euryarchaeota*) [48] A major group of archaeans [3], diagnosed on the basis of rRNA sequences. Includes many methanogens, extreme halophiles, and thermophiles.

eutherians (*Eutheria*) A group of viviparous mammals [129], eutherians are well developed at birth (contrast to prototherians and marsupials, the other two groups of mammals). Most familiar mammals outside the Australian and South American regions are eutherians (see Table 33.1).

excavates (*Excavata*) [8] Diverse group of unicellular, flagellate eukaryotes, many of which possess a feeding groove; some lack mitochondria.

- F -

ferns Vascular plants [12] usually possessing large, frondlike leaves that unfold from a “fiddlehead.” Not a monophyletic group, although most fern species are encompassed in a monophyletic clade, the leptosporangiate ferns [73].

flatworms (*Platyhelminthes*) [100] A group of dorsoventrally flattened and generally elongate soft-bodied lophotrochozoans [24]. May be free-living or parasitic, found in marine, freshwater, or damp terrestrial environments. Major flatworm groups include the tapeworms, flukes, monogeneans, and turbellarians.

flowering plants See angiosperms [15].

flukes (*Trematoda*) A group of wormlike parasitic flatworms [100] with complex life cycles that involve several different host species. May be paraphyletic with respect to tapeworms.

foraminiferans (*Foraminifera*) [57] Amoeboid organisms with fine, branched pseudopods that form a food-trapping net. Most produce external shells of calcium carbonate.

fungi (*Fungi*) [17] Eukaryotic heterotrophs with absorptive nutrition based on extracellular digestion; cell walls contain chitin. Major fungal groups include the microsporidia [85], “chytrids” [86], “zygospore fungi” [87], arbuscular mycorrhizal fungi [88], sac fungi [89], and club fungi [90].

- G -

gastropods (*Gastropoda*) The largest group of mollusks [106]. Gastropods possess a well-defined head with two or four sensory tentacles (often terminating in eyes) and a ventral foot. Most species have a single coiled or spiraled shell. Common in marine, freshwater, and terrestrial environments.

gastrotrichs (*Gastrotricha*) [101] Tiny (0.06–3.0 mm), elongate acelomate lophotrochozoans [24] that are covered in cilia. They live in marine, freshwater, and wet terrestrial habitats. They are simultaneous hermaphrodites.

ginkgo (*Ginkgoophyta*) [75] A gymnosperm [14] group with only one living species. The ginkgo seed is surrounded by a fleshy tissue not derived from an ovary wall and hence not a fruit.

glass sponges (*Hexactinellida*) [92] Sponges [20] with a skeleton composed of four- and/or six-pointed spicules made of silica.

glaucomphytes (*Glaucomphyta*) [63] Unicellular freshwater algae with chloroplasts containing traces of peptidoglycan, the characteristic cell wall material of bacteria.

gnathostomes (*Gnathostomata*) See jawed vertebrates [32].

gnetophytes (*Gnetophyta*) [76] A gymnosperm [14] group with three very different lineages; all have wood with vessels, unlike other gymnosperms.

green plants (*Viridiplantae*) [10] Organisms with chlorophylls *a* and *b*, cellulose-containing cell walls, starch as a carbohydrate storage product, and chloroplasts surrounded by two membranes.

gymnosperms (*Gymnospermae*) [14] Seed plants [13] with seeds “naked” (i.e., not enclosed in carpels). Probably monophyletic, but status still in doubt. Includes the conifers [77], gnetophytes [76], ginkgo [75], and cycads [74].

- H -

hadobacteria (*Hadobacteria*) [42] A group of extremophilic bacteria [2] that includes the genera *Deinococcus* and *Thermus*.

hagfishes (*Myxini*) [122] Elongate, slimy-skinned vertebrates [31] with three small accessory hearts, a partial cranium, and no stomach or paired fins. See also craniata; cyclostomes.

hemichordates (*Hemichordata*) [119] One of the two primary groups of ambulacrarians [29];

marine wormlike organisms with a three-part body plan.

heteroloboseans (*Heterolobosea*) [60] Colorless excavates [8] that can transform among amoeboid, flagellate, and encysted stages.

hexapods (*Hexapoda*) [117] Major group of arthropods [26] characterized by a reduction (from the ancestral arthropod condition) to six walking appendages, and the consolidation of three body segments to form a thorax. Includes insects and their relatives (see Table 23.2).

high-GC Gram-positives (*Actinobacteria*) [40] Gram-positive bacteria with a relatively high (G+C)/(A+T) ratio of their DNA, with a filamentous growth habit.

hornworts (*Anthocerotophyta*) [70] Nonvascular plants with sporophytes that grow from the base. Cells contain a single large, platelike chloroplast.

horsehair worms (*Nematomorpha*) [110] A group of very thin, elongate, wormlike freshwater ecdysozoans [25]. Largely nonfeeding as adults, they are parasites of insects and crayfish as larvae.

horseshoe crabs (*Xiphosura*) Marine chelicerates [114] with a large outer shell in three parts: a carapace, an abdomen, and a tail-like telson. There are only five living species, but many additional species are known from fossils.

horsetails (*Sphenophyta* or *Equisetophyta*) [72] Vascular plants [12] with reduced megaphylls in whorls.

hydrozoans (*Hydrozoa*) A group of cnidarians [97]. Most species go through both polyp and mesoda stages, although one stage or the other is eliminated in some species.

hyperthermophilic bacteria [41] A group of thermophilic bacteria [2] that live in volcanic vents, hot springs, and in underground oil reservoirs; includes the genera *Aquifex* and *Thermotoga*.

- I -

insects (*Insecta*) The largest group within the hexapods [117]. Insects are characterized by exposed mouthparts and one pair of antennae containing a sensory receptor called a Johnston's organ. Most have two pairs of wings as adults. There are more described species of insects than all other groups of life [1] combined, and many species remain to be discovered. The major insect groups are described in Table 23.2.

"invertebrates" Convenience term encompassing any animal [19] that is not a vertebrate [31].

isopods (*Isopoda*) Crustaceans [116] characterized by a compact head, unstalked compound eyes, and mouthparts consisting of four pairs of appendages. Isopods are abundant and widespread in salt, fresh, and brackish water, although some species (the sow bugs) are terrestrial.

- J -

jawed vertebrates (*Gnathostomata*) [32] A major group of vertebrates [31] with jawed mouths. Includes chondrichthyans [124], ray-finned fishes [125], and lobe-limbed vertebrates [34].

- K -

kinetoplastids (*Kinetoplastida*) [62] Unicellular, flagellate organisms characterized by the presence in their single mitochondrion of a kinetoplast (a structure containing multiple, circular DNA molecules).

kinorhynchs (*Kinorhyncha*) [108] Small (< 1 mm) marine ecdysozoans [25] with bodies in 13 segments and a retractable proboscis.

korarchaeotes (*Korarchaeota*) A group of archaeans [3] known only by evidence from nucleic acids derived from hot springs. Its phylogenetic relationships within the Archaea are unknown.

krill (*Euphausiacea*) A group of shrimplike marine crustaceans [116] that are important components of the zooplankton.

- L -

lampreys (*Petromyzontiformes*) [123] Elongate, eel-like vertebrates [31] that often have rasping and sucking disks for mouths.

lancelets (*Cephalochordata*) [120] A group of weakly swimming, eel-like benthic marine chordates [30].

land plants (*Embryophyta*) [11] Plants with embryos that develop within protective structures; also called embryophytes. Sporophytes and gametophytes are multicellular. Land plants possess a cuticle. Major groups are the liverworts [68], mosses [69], hornworts [70], and vascular plants [12].

larvaceans (*Larvacea*) Solitary, planktonic tunicates [121] that retain both notochords and nerve cords throughout their lives.

lepidosaurs (*Lepidosauria*) [130] Reptiles [37] with overlapping scales. Includes tuataras and squamates (lizards, snakes, and amphisbaenians).

leptosporangiate ferns (*Pteridopsida* or *Polypodiopsida*) [73] Vascular plants [12] usually possessing large, frondlike leaves that unfold from a "fiddlehead," and possessing thin-walled sporangia.

life (*Life*) [1] The monophyletic group that includes all known living organisms. Characterized by a nucleic-acid based genetic system (DNA or RNA), metabolism, and cellular structure. Some parasitic forms, such as viruses, have secondarily lost some of these features and rely on the cellular environment of their host.

liverworts (*Hepatophyta*) [68] Nonvascular plants lacking stomata; stalk of sporophyte elongates along its entire length.

lobe-limbed vertebrates (*Sarcopterygii*) [34] One of the two major groups of bony vertebrates [33], characterized by jointed appendages (paired fins or limbs).

loboseans (*Lobosea*) A group of unicellular amoebozoans [84]; includes the most familiar amoebas (e.g., *Amoeba proteus*).

"lophophorates" Convenience term used to describe several groups of lophotrochozoans [24] that have a feeding structure called a lophophore (a circular or U-shaped ridge around the mouth that bears one or two rows of ciliated, hollow tentacles). Not a monophyletic group.

lophotrochozoans (*Lophotrochozoa*) [24] One of the two main groups of protostomes

[23]. This group is morphologically diverse, and is supported primarily on information from gene sequences. Includes bryozoans and entoprocts [99], flatworms [100], rotifers and gastrotrichs [101], ribbon worms [102], brachiopods [103], phoronids [104], annelids [105], and mollusks [106].

loriciferans (*Loricifera*) [109] Small (< 1 mm) ecdysozoans [25] with bodies in four parts, covered with six plates.

low-GC Gram-positives (*Firmicutes*) [39] A diverse group of bacteria [2] with a relatively low (G+C)/(A+T) ratio of their DNA, often but not always Gram-positive, some producing endospores.

lungfishes (*Dipnoi*) [127] A group of aquatic lobe-limbed vertebrates [34] that are the closest living relatives of the tetrapods [35]. They have a modified swim bladder used to absorb oxygen from air, so some species can survive the temporary drying of their habitat.

lycophytes (*Lycopodiophyta*) [71] Vascular plants [12] characterized by microphylls; includes club mosses, spike mosses, and quillworts.

- M -

magnoliids (*Magnoliidae*) [81] A major group of angiosperms [15] possessing two cotyledons and pollen grains with a single opening. The group is defined primarily by nucleotide sequence data; it is more closely related to the eudicots and monocots than to three other small angiosperm groups.

mammals (*Mammalia*) [129] A group of tetrapods [35] with hair covering all or part of their skin; -females produce milk to feed their developing young. Includes the prototherians, marsupials, and -eutherians.

mandibulates (*Mandibulata*) [27] Arthropods [26] that include mandibles as mouth parts. Includes myriapods [115], crustaceans [116], and hexapods [117].

marsupials (*Marsupialia*) Mammals [129] in which the female typically has a marsupium (a pouch for rearing young, which are born at an extremely early stage in development). Includes such familiar mammals as opossums, koalas, and kangaroos.

metazoans (*Metazoa*) See animals [19].

microbial eukaryotes See "protists."

microsporidia (*Microsporidia*) [85] A group of parasitic unicellular fungi [17] that lack mitochondria and have walls that contain chitin.

mollusks (*Mollusca*) [106] One of the major groups of lophotrochozoans [24], mollusks have bodies composed of a foot, a mantle (which often secretes a hard, calcareous shell), and a visceral mass. Includes monoplacophorans, chitons, bivalves, gastropods, and cephalopods.

monilophytes (*Monilophyta*) A group of vascular plants [12], sister to the seed plants [13], characterized by overtopping and possession of megaphylls; includes the horsetails [72] and ferns [73].

monocots (*Monocotyledones*) [82] Angiosperms [15] characterized by possession of a single cotyledon, usually parallel leaf veins, a fibrous root system, pollen grains with a single

opening, and floral organs usually in multiples of three.

monogeneans (*Monogenea*) A group of ectoparasitic flatworms [100].

monoplacophorans (*Monoplacophora*) Mollusks [106] with segmented body parts and a single, thin, flat, rounded, bilateral shell.

mosses (*Bryophyta*) [69] Nonvascular plants with true stomata and erect, “leafy” gametophytes; sporophytes elongate by apical cell division.

moss animals See bryozoans [99].

myriapods (*Myriapoda*) [115] Arthropods [26] characterized by an elongate, segmented trunk with many legs. Includes centipedes and millipedes.

– N –

nanoarchaeotes (*Nanoarchaeota*) A group of extremely small, thermophilic archaeans [3] with a much-reduced genome. The only described example can survive only when attached to a host organism.

nematodes (*Nematoda*) [111] A very large group of elongate, unsegmented ecdysozoans [25] with thick, multilayer cuticles. They are among the most abundant and diverse animals, although most species have not yet been described. Include free-living predators and scavengers, as well as parasites of most species of land plants [11] and animals [19].

neognaths (*Neognathae*) The main group of birds [132], including all living species except the ratites (ostrich, emu, rheas, kiwis, cassowaries) and tinamous. See palaeognaths.

– O –

oligochaetes (*Oligochaeta*) Annelid [105] group whose members lack parapodia, eyes, and anterior tentacles, and have few setae. Earthworms are the most familiar oligochaetes.

onychophorans (*Onychophora*) [113] Elongate, segmented ecdysozoans [25] with many pairs of soft, unjointed, claw-bearing legs. Also known as velvet worms.

oomycetes (*Oomycota*) [52] Water molds and relatives; absorptive heterotrophs with nutrient-absorbing, filamentous hyphae.

opisthokonts (*Opisthokonta*) [16] A group of eukaryotes [4] in which the flagellum on motile cells, if present, is posterior. The opisthokonts include the fungi [17], animals [19], and choanoflagellates [91].

ostracods (*Ostracoda*) Marine and freshwater crustaceans [116] that are laterally compressed and protected by two clamlike calcareous or chitinous shells.

– P –

palaeognaths (*Palaeognathae*) A group of secondarily flightless or weakly flying birds [132]. Includes the flightless ratites (ostrich, emu, rheas, kiwis, cassowaries) and the weakly flying tinamous.

parabasals (*Parabasalia*) [59] A group of unicellular eukaryotes [4] that lack mitochondria; they possess flagella in clusters near the anterior of the cell.

phoronids (*Phoronida*) [104] A small group of sessile, wormlike marine lophotrochozoans

[24] that secrete chitinous tubes and feed using a lophophore.

placoderms (*Placodermi*) An extinct group of jawed vertebrates [32] that lacked teeth. Placoderms were the dominant predators in Devonian oceans.

placozoans (*Placozoa*) [96] A poorly known group of structurally simple, asymmetrical, flattened, transparent animals found in coastal marine tropical and subtropical seas. Most evidence suggests that placozoans are secondarily simplified eumetazoans [21].

Plantae [9] The most broadly defined plant group. In most parts of this book, we use the word “plant” as synonymous with “land plant” [11], a more restrictive definition.

plasmodial slime molds (*Myxogastriada*) Amoebozoans [84] that in their feeding stage consist of a coenocyte called a plasmodium.

pogonophorans (*Pogonophora*) Deep-sea annelids [105] that lack a mouth or digestive tract; they feed by taking up dissolved organic matter, facilitated by endosymbiotic bacteria in a specialized organ (the trophosome).

polychaetes (*Polychaeta*) A group of mostly marine annelids [105] with one or more pairs of eyes and one or more pairs of feeding tentacles; parapodia and setae extend from most body segments. May be paraphyletic with respect to the clitellates.

priapulids (*Priapulida*) [107] A small group of cylindrical, unsegmented, wormlike marine ecdysozoans [25] that takes its name from its phallic appearance.

“prokaryotes” Not a monophyletic group; as commonly used, includes the bacteria [2] and archaeans [3]. A term of convenience encompassing all cellular organisms that are not eukaryotes.

proteobacteria (*Proteobacteria*) [44] A large and extremely diverse group of Gram-negative bacteria that includes many pathogens, nitrogen fixers, and photosynthesizers. Includes the alpha, beta, gamma, delta, and epsilon proteobacteria.

“protists” This term of convenience is used to encompass a large number of distinct and distantly related groups of eukaryotes, many but far from all of which are microbial and unicellular. Essentially a “catch-all” term for any eukaryote group not contained within the land plants [11], fungi [17], or animals [19].

protostomes (*Protostomia*) [23] One of the two major groups of bilaterians [22]. In protostomes, the mouth typically forms from the blastopore (if present) in early development (contrast with deuterostomes). The major protostome groups are the lophotrochozoans [24] and ecdysozoans [25].

prototherians (*Prototheria*) A mostly extinct group of mammals [129], common during the Cretaceous and early Cenozoic. The five living species—four echidnas and the duck-billed platypus—are the only extant egg-laying mammals.

pterobranchs (*Pterobranchia*) A small group of sedentary marine hemichordates [119] that live in tubes secreted by the proboscis. They

have one to nine pairs of arms, each bearing long tentacles that capture prey and function in gas exchange.

pyncnogonids (*Pyncnogonida*) Treated in this book as a group of chelicerates [114], but sometimes considered an independent group of arthropods [26]. Pyncnogonids have reduced bodies and very long, slender legs. Also called sea spiders.

– R –

radiolarians (*Radiolaria*) [55] Amoeboid organisms with needlelike pseudopods supported by microtubules. Most have glassy internal skeletons.

ray-finned fishes (*Actinopterygii*) [125] A highly diverse group of freshwater and marine bony vertebrates [33]. They have reduced swim bladders that often function as hydrostatic organs and fins supported by soft rays (lepidotrichia). Includes most familiar fishes.

red algae (*Rhodophyta*) [64] Mostly multicellular, marine and freshwater algae characterized by the presence of phycoerythrin in their chloroplasts.

reptiles (*Reptilia*) [37] One of the two major groups of extant amniotes [36], supported on the basis of similar skull structure and gene sequences. The term “reptiles” traditionally excluded the birds [132], but the resulting group is then clearly paraphyletic. As used in this book, the reptiles include turtles [131], lepidosaurs [130], birds [132], and crocodilians [133].

rhizaria (*Rhizaria*) [7] Mostly amoeboid unicellular eukaryotes with pseudopods, many with external or internal shells. Includes the foraminiferans [57], cercozoans [56], and radiolarians [55].

rhyniophytes (*Rhyniophyta*) A group of early vascular plants [12] that appeared in the Silurian and became extinct in the Devonian. Possessed dichotomously branching stems with terminal sporangia but no true leaves or roots.

ribbon worms (*Nemertea*) [102] A group of unsegmented lophotrochozoans [24] with an eversible proboscis used to capture prey. Mostly marine, but some species live in fresh water or on land.

rotifers (*Rotifera*) [101] Tiny (<0.5 mm) lophotrochozoans [24] with a pseudocoelomic body cavity that functions as a hydrostatic organ, and a ciliated feeding organ called the corona that surrounds the head. Rotifers live in freshwater and wet terrestrial habitats.

roundworms (*Nematoda*) [111] See nematodes.

– S –

sac fungi (*Ascomycota*) [89] Fungi that bear the products of meiosis within sacs (asci) if the organism is multicellular. Some are unicellular.

salamanders (*Caudata*) A group of amphibians [128] with distinct tails in both larvae and adults and limbs set at right angles to the body.

salps See thaliaceans.

sarcopterygians (*Sarcopterygii*) [34] See lobe-limbed vertebrates.

scyphozoans (*Scyphozoa*) Marine cnidarians [97] in which the medusa stage dominates the life cycle. Commonly known as jellyfish.

sea cucumbers (*Holothuroidea*) Echinoderms [118] with an elongate, cucumber-shaped body and leathery skin. They are scavengers on the ocean floor.

sea spiders See pycnogonids.

sea squirts See ascidians.

sea stars (*Asteroidea*) Echinoderms [118] with five (or more) fleshy “arms” radiating from an indistinct central disk. Also called starfishes.

sea urchins (*Echinoidea*) Echinoderms [118] with a test (shell) that is covered in spines. Most are globular in shape, although some groups (such as the sand dollars) are flattened.

“seed ferns” A paraphyletic group of loosely related, extinct seed plants that flourished in the Devonian and Carboniferous. Characterized by large, frondlike leaves that bore seeds.

seed plants (*Spermatophyta*) [13] Heterosporous vascular plants [12] that produce seeds; most produce wood; branching is axillary (not dichotomous). The major seed plant groups are gymnosperms [14] and angiosperms [15].

sow bugs See isopods.

spirochetes (*Spirochaetes*) [45] Motile, Gram-negative bacteria with a helically coiled structure and characterized by axial filaments.

sponges (*Porifera*) [20] A group of relatively asymmetric, filter-feeding animals that lack a gut or nervous system and generally lack differentiated tissues. Includes glass sponges [92], demosponges [93], and calcareous sponges [94].

springtails (*Collembola*) Wingless hexapods [117] with springing structures on the third and fourth segments of their bodies. Springtails are extremely abundant in some environments (especially in soil, leaf litter, and vegetation).

squamates (*Squamata*) The major group of lepidosaurs [130], characterized by the possession of movable quadrate bones (which allow the upper jaw to move independently of the rest of the skull) and hemipenes (a paired set of eversible penises, or penes) in males. Includes the lizards (a paraphyletic group), snakes, and amphisbaenians.

star anise (*Austrobaileyales*) [80] A group of woody angiosperms [15] thought to be the sister-group of the clade of flowering plants that includes eudicots [83], monocots [82], and magnoliids [81].

starfish (*Asteroidea*) See sea stars.

stoneworts (*Charales*) [67] Multicellular green algae with branching, apical growth and plasmodesmata between adjacent cells. The closest living relatives of the land plants [11], they retain the egg in the parent organism.

stramenopiles (*Heterokonta* or *Stramenopila*) [6] Organisms having, at some stage in their life cycle, two unequal flagella, the longer possessing rows of tubular hairs. Chloroplasts, when present, surrounded by four membranes. Major stramenopile groups include the brown algae [54], diatoms [53], and oomycetes [52].

- T -

tapeworms (*Cestoda*) Parasitic flatworms [100] that live in the digestive tracts of vertebrates as adults, and usually in various other species of animals as juveniles.

tardigrades (*Tardigrada*) [112] Small (< 0.5 mm) ecdysozoans [25] with fleshy, unjointed legs and no circulatory or gas exchange organs. They live in marine sands, in temporary freshwater pools, and on the water films of plants. Also called water bears.

tetrapods (*Tetrapoda*) [35] The major group of lobe-limbed vertebrates [34]; includes the amphibians [128] and the amniotes [36]. Named for the presence of four jointed limbs (although limbs have been secondarily reduced or lost completely in several tetrapod groups).

thaliaceans (*Thaliacea*) A group of solitary or colonial planktonic marine tunicates [121]. Also called salps.

therians (*Theria*) Mammals [129] characterized by viviparity (live birth). Includes eutherians and marsupials.

theropods (*Theropoda*) Archosaurs [38] with bipedal stance, hollow bones, a furcula (“wish-bone”), elongated metatarsals with three-fingered feet, and a pelvis that points backwards. Includes many well-known extinct dinosaurs (such as *Tyrannosaurus rex*), as well as the living birds [132].

tracheophytes See vascular plants [12].

trilobites (*Trilobita*) An extinct group of arthropods [26] related to the chelicerates [114]. Trilobites flourished from the Cambrian through the Permian.

tuataras (*Rhynchocephalia*) A group of lepidosaurs [130] known mostly from fossils; there are

only two living tuatara species. The quadrate bone of the upper jaw is fixed firmly to the skull. Sister group of the squamates.

tunicates (*Tunicata*) [121] A group of chordates [30] that are mostly saclike filter feeders as adults, with motile larval stages that resemble tadpoles.

turbellarians (*Turbellaria*) A group of free-living, generally carnivorous flatworms [100]. Their monophyly is questionable.

turtles (*Testudines*) [131] A group of reptiles [37] with a bony carapace (upper shell) and plastron (lower shell) that encase the body in a fashion unique among the vertebrates.

- U -

urochordates (*Tunicata*) [121] See tunicates.

- V -

vascular plants (*Tracheophyta*) [12] Plants with xylem and phloem. Major groups include the lycophytes [71] and euphyllophytes.

vertebrates (*Vertebrata*) [31] The largest group of chordates [30], characterized by a rigid endoskeleton supported by the vertebral column and an anterior skull encasing a brain. Includes hagfishes [122], lampreys [123], and the jawed vertebrates [32], although some biologists exclude the hagfishes from this group. See also craniates.

- W -

water bears See tardigrades.

water lilies (*Nymphaeaceae*) [79] A group of aquatic, freshwater angiosperms [15] that are rooted in soil in shallow water, with round floating leaves and flowers that extend above the water’s surface. They are the sister-group to most of the remaining flowering plants, with the exception of the genus *Amborella* [78].

- Y -

“yeasts” Convenience term for several distantly related groups of unicellular fungi [17].

- Z -

“zygospore fungi” (*Zygomycota*, if monophyletic) [87] A convenience term for a probably paraphyletic group of fungi [17] in which hyphae of differing mating types conjugate to form a zygosporangium.

Appendix B Statistics Primer

This appendix is designed to help you conduct simple statistical analyses and understand their application and importance. This introduction will help you complete the Apply the Concept and Analyze the Data problems throughout this book. The formulas for a number of statistical tests are presented here, but the presentation is designed primarily to help you understand the purpose and reasoning of the various tests. Once you understand the basis of the analysis, you may wish to use one of many free, online web sites for conducting the tests and calculating relevant test statistics (such as <http://faculty.vassar.edu/lowry/VassarStats.html>).

Why Do We Do Statistics?

ALMOST EVERYTHING VARIES We live in a variable world, but within the variation we see among biological organisms there are predictable patterns. We use statistics to find and analyze these patterns. Consider any group of common things in nature—all women aged 22, all the cells in your liver, or all the blades of grass in your yard. Although they will have many similar characteristics, they will also have important differences. Men aged 22 tend to be taller than women aged 22, but, of course, not every man will be taller than every woman in this age group.

Natural variation can make it difficult to find general patterns. For example, scientists have determined that smoking increases the risk of getting lung cancer. But we know that not all smokers will develop lung cancer and not all nonsmokers will remain cancer-free. If we compare just one smoker to just one nonsmoker, we may end up drawing the wrong conclusion. So how did scientists discover this general pattern? How many smokers and nonsmokers did they examine before they felt confident about the risk of smoking?

Statistics helps us to find general patterns, even when nature does not always follow those patterns.

AVOIDING FALSE POSITIVES AND FALSE NEGATIVES When a woman takes a pregnancy test, there is some chance that it will be positive even if she is not pregnant, and there is some chance that it will be negative even if she is pregnant. We call these kinds of mistakes *false positives* and *false negatives*.

Doing science is a bit like taking a medical test. We observe patterns in the world, and we try to draw conclusions about how the world works from those observations. Sometimes our observations lead us to draw the wrong conclusions. We might conclude that a phenomenon occurs, when it actually does not;

or we might conclude that a phenomenon does not occur, when it actually does.

For example, the planet Earth has been warming over the past century (see Concept 46.4). Ecologists are interested in whether plant and animal populations have been affected by global warming. If we have long-term information about the locations of species and temperatures in certain areas, we can determine whether species movements coincide with temperature changes. Such information can, however, be very complicated. Without proper statistical methods, one may not be able to detect the true impact of temperature or, instead, may think a pattern exists when it does not.

Statistics helps us to avoid drawing the wrong conclusions.

How Does Statistics Help Us Understand the Natural World?

Statistics is essential to scientific discovery. Most biological studies involve five basic steps, each of which requires statistics:

- **Step 1: Experimental Design**
Clearly define the scientific question and the methods necessary to tackle the question.
- **Step 2: Data Collection**
Gather information about the natural world through experiments and field studies.
- **Step 3: Organize and Visualize the Data**
Use tables, graphs, and other useful representations to gain intuition about the data.
- **Step 4: Summarize the Data**
Summarize the data with a few key statistical calculations.
- **Step 5: Inferential Statistics**
Use statistical methods to draw general conclusions from the data about the way the world works.

Step 1: Experimental Design

We conduct experiments to gain knowledge about the world. Scientists come up with scientific ideas based on prior research and their own observations. These ideas may take the form of a question like “Does smoking cause cancer?,” a hypothesis like “Smoking increases the risk of cancer,” or a prediction like “If a person smokes, he/she will increase his/her chances of developing cancer.” Experiments allow us to test such scientific ideas, but designing a good experiment can be quite challenging.

We use statistics to guide us in designing experiments so that we end up with the right kinds of data. Before embarking on an experiment, we use statistics to determine how much data will be required to test our idea, and to prevent extraneous factors from misleading us. For example, suppose we want to conduct an experiment on fertilizers to test the hypothesis that nitrogen increases plant growth. If we include too few plants, we will not be able to determine whether or not nitrogen has an effect on growth, and the experiment will be for naught. If we include too many plants, we will waste valuable time and resources. Furthermore, we should design the experiment so that we can detect differences that are actually caused by nitrogen fertilization rather than by variation, for example, in sunlight or precipitation experienced by the plants.

Step 2: Data Collection

TAKING SAMPLES When biologists gather information about the natural world, they typically collect a few representative pieces of information. For example, when evaluating the efficacy of a candidate drug for medulloblastoma brain cancer, scientists may test the drug on tens or hundreds of patients, and then draw conclusions about its efficacy for all patients with these tumors. Similarly, scientists studying the relationship between body weight and clutch size (number of eggs) for female spiders of a particular species may examine tens to hundreds of spiders to make their conclusions.

We use the expression “sampling from a population” to describe this general method of taking representative pieces of information from the system under investigation (Figure B1). The pieces of information in a **sample** are called **observations**. In the cancer therapy example, each observation was the change in a patient’s tumor size six months after initiating treatment, and the population of interest was all individuals with medulloblastoma tumors. In the spider example, each observation was a pair of measurements—body size and clutch size—for a single female spider, and the population of interest was all female spiders of this species.

Sampling is a matter of necessity, not laziness. We cannot hope (and would not want) to collect *all* of the female spiders of the species of interest on Earth! Instead, we use statistics to determine how many spiders we must collect in order to confidently infer something about the general population and then use statistics again to make such inferences.

FIGURE B1 Sampling From a Population Biologists take representative samples from a population, use descriptive statistics to characterize their samples, and then use inferential statistics to draw conclusions about the original population.

TABLEB1 Poinsettia Colors

Color	Frequency	Proportion
Red	108	0.59
Pink	34	0.19
White	40	0.22
Total	182	1.00

DATA COME IN ALL SHAPES AND SIZES In statistics, we use the word *variable* to mean a measurable characteristic of an individual or a system. Some variables are on a numerical scale, like the daily high temperature (a numerical value constrained by the precision of our thermometer), or the clutch size of a spider (a whole number: 0, 1, 2, 3,...). We call these **quantitative variables**. Quantitative variables that only take on whole number values are called **discrete variables**, whereas variables that can also take on any fractional value are called **continuous variables**.

Other variables take categories as values, like a human blood type (A, B, AB, or O) or an ant caste (queen, worker, or male). We call these **categorical variables**. Categorical variables with a natural ordering, like a final grade in Introductory Biology (A, B, C, D, or F), are called **ordinal variables**.

Each class of variables comes with its own set of statistical methods. We will introduce a few common methods in this Appendix that will help you work on the problems presented in this book, but you should consult a biostatistics textbook for more advanced tests and analyses for other data sets and problems.

Step 3: Organize and Visualize the Data

Tables and graphs can help you gain intuition about your data, design appropriate statistical tests, and anticipate the outcome of your analysis. A **frequency distribution** lists all possible values and the number of occurrences of each value in the sample.

TABLEB2 Fish Weights of *Abramis brama* from Lake Laengelmavesi

Weight (grams)	Frequency	Relative Frequency
201–300	2	0.06
301–400	3	0.09
401–500	8	0.24
501–600	3	0.09
601–700	8	0.24
701–800	3	0.09
801–900	1	0.03
901–1000	6	0.18
Total	34	1.00

B2 Bar Charts Compare Categorical Data This bar chart shows the frequency of three poinsettia colors that result from an experimental cross.

Table B1 shows a frequency distribution of the colors of 182 poinsettia plants (red, pink, or white) resulting from an experimental cross between two parent plants. For categorical data like this, we can visualize the frequency distribution by constructing a **bar chart**. The heights of the bars indicate the number of observations in each category (**Figure B2**). Another way to display the same data is in a **pie chart**, which shows the proportion of each category represented like pieces of a pie (**Figure B3**).

For quantitative data, it is often useful to condense your data by grouping (or binning) it into **classes**. In **Table B2**, we see a grouped frequency distribution of fish weights for a sample of 34 fish (*Abramis brama*) caught in Lake Laengelmavesi in Finland. The second column (*Frequency*) gives the number of observations in each class and the third column (*Relative Frequency*) gives the overall proportion of observations falling into each class.

Histograms depict frequency distributions for quantitative data. The histogram in **Figure B4** shows the relative frequencies of each weight class in this study. When grouping quantitative data, it is necessary to decide how many classes to include. It is often useful to look at multiple histograms before deciding which grouping offers the best representation of the data.

B3 Pie Charts Show Proportions of Categories This pie chart shows the proportions of the three poinsettia colors presented in Table B1.

B4 Histograms Depict Frequency Distributions of Quantitative Data This histogram shows the relative frequency of different weight-classes of fish (*Abramis brama*).

Sometimes we wish to compare two quantitative variables. For example, the researchers at Lake Laengelmavesi investigated the relationship between fish weight and length and thus also measured the length of each fish. We can visualize this relationship using a **scatter plot** in which the weight and length of each fish is represented as a single point (**Figure B5**). We say that these two variables have a **linear relationship** since the points in their scatter plot fall roughly on a straight line.

Tables and graphs are critical to interpreting and communicating data, and thus should be as self-contained and comprehensible as possible. Their content should be easily understood simply by looking at them. Axes, captions, and units should be clearly labeled, statistical terms should be defined, and appropriate groupings should be used when tabulating or graphing quantitative data.

B5 Scatter Plots Contrast Two Variables Scatter plot of *Abramis brama* weights and lengths (measured from nose to end of tail). These two variables have a linear relationship since the data points lie close to a straight line.

Step 4: Summarize the Data

A **statistic** is a numerical quantity calculated from data, while **descriptive statistics** are quantities that describe general patterns in data. Descriptive statistics allow us to make straightforward comparisons between different data sets and concisely communicate basic features of our data.

DESCRIBING CATEGORICAL DATA For categorical variables, we typically use proportions to describe our data. That is, we construct tables containing the proportions of observations in each category. For example, the third column in Table B1 provides the proportions of poinsettia plants in each color category, and the pie chart in Figure B3 provides a visual representation of those proportions.

DESCRIBING QUANTITATIVE DATA For quantitative data, we often start by calculating the average value or **mean** of our sample. This familiar quantity is simply the sum of all the values in the sample divided by the number of observations in our sample (**Figure B6**). The mean is only one of several quantities that roughly tell us where the *center* of our data lies. We call these quantities **measures of center**. Other commonly used measures of center are the **median**—the value that literally lies

B7 Measures of Dispersion Two samples with the same mean (black horizontal lines) and range (blue vertical line). Red lines show the deviations of each observation from the mean. Samples with large deviations have large standard deviations. The left sample has a smaller standard deviation than the right sample.

in the middle of the sample—and the **mode**—the most frequent value in the sample.

It is often just as important to quantify the variation in the data as it is to calculate its center. There are several statistics that tell us how much the values differ from one another. We call these **measures of dispersion**. The easiest to understand and calculate is the **range**, which is simply the largest value in the sample minus the smallest value. The most commonly used measure of dispersion is the **standard deviation**, which calculates the extent to which the data are spread out from the mean. A deviation is the difference between an observation and the mean of the sample, and the standard deviation is a number that summarizes all of the deviations. Two samples can have the same range, but very different standard deviations if one is clustered closer to the mean than the other. In **Figure B7**, for example, the left sample has a lower standard deviation ($s = 2.6$) than the right sample ($s = 3.6$), even though the two samples have the same means and ranges.

To demonstrate these descriptive statistics, we return to the Lake Laengelmavesi study. The researchers also caught and recorded the weights of six fish in the species *Leusiscus idus*: 270, 270, 306, 540, 800, and 1,000 grams. The mean weight in this sample (equation 1 in Figure B6) is:

$$\bar{x} = \frac{\sum x_i}{n} = \frac{270 + 270 + 306 + 540 + 800 + 1000}{6} = 531$$

Since there is an even number of observations in the sample, then the median weight is the value halfway between the two middle values:

$$\frac{306 + 540}{2} = 423$$

The mode of the sample is 270, the only value that appears more than once. The standard deviation (equation 2 in Figure B6) is:

RESEARCH TOOLS

B6 Descriptive Statistics for Quantitative Data

Below are the equations used to calculate the descriptive statistic we discuss in this appendix. You can calculate these statistics yourself, or use free internet resources to help you make your calculations.

Notation:

$x_1, x_2, x_3, \dots, x_n$ are the n observations of variable X in the sample.

$\sum_{i=1}^n x_i = x_1 + x_2 + x_3 + \dots + x_n$ is the sum of all of the observations. (The Greek letter sigma, Σ , is used to denote "sum of.")

In regression, the independent variable is X , and the dependent variable is Y . b_0 is the vertical intercept of a regression line. b_1 is the slope of a regression line.

Equations

1. Mean: $\bar{x} = \frac{\sum_{i=1}^n x_i}{n}$

2. Standard deviation: $s = \sqrt{\frac{\sum (x_i - \bar{x})^2}{n - 1}}$

3. Correlation coefficient: $r = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum (x_i - \bar{x})^2 \sum (y_i - \bar{y})^2}}$

4. Least-squares regression line: $Y = b_0 + b_1 X$
where $b_1 = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{\sum (x_i - \bar{x})^2}$ and $b_0 = \bar{y} - b_1 \bar{x}$

B8 Correlation Coefficients The correlation coefficient (r) indicates both the strength and the direction of the relationship.

$$s = \sqrt{\frac{(270-531)^2 + (270-531)^2 + (306-531)^2 + (540-531)^2 + (800-531)^2 + (1000-531)^2}{5}} = 309.6$$

and the range is $1000 - 270 = 730$.

DESCRIBING THE RELATIONSHIP BETWEEN TWO QUANTITATIVE VARIABLES Biologists are often interested in understanding the relationship between two different quantitative variables: How does the height of an organism relate to its weight? How does air pollution relate to the prevalence of asthma? How does lichen abundance relate to levels of air pollution? Recall that scatter plots visually represent such relationships.

We can quantify the strength of the relationship between two quantitative variables using a single value called the Pearson product-moment **correlation coefficient** (equation 3 in Figure B6). This statistic ranges between -1 and 1 , and tells us how closely the points in a scatter plot conform to a straight line. A negative correlation coefficient indicates that one variable decreases as the other increases; a positive correlation coefficient indicates that the two variables increase together, and a correlation coefficient of zero indicates that there is no linear relationship between the two variables (Figure B8).

One must always keep in mind that *correlation does not mean causation*. Two variables can be closely related without one causing the other. For example, the number of cavities in a child's mouth correlates positively with the size of their feet. Clearly cavities do not enhance foot growth; nor does foot growth cause tooth decay. Instead the correlation exists because both quantities tend to increase with age.

Intuitively, the straight line that tracks the cluster of points on a scatter plot tells us something about the *typical* relationship between the two variables. Statisticians do not, however, simply eyeball the data and draw a line by hand. They often use a method called least-squares **linear regression** to fit a straight line to the data (equation 4 in Figure B6). This method calculates the line that minimizes the overall vertical distances between the points in the scatter plot and the line itself. These distances are called **residuals** (Figure B9). Two parameters

B9 Linear Regression Estimates the Typical Relationship Between Two Variables Linear-least squares regression line for *Abramis brama* weights and lengths (measured from nose to end of tail). The regression line (blue line) is given by the equation $Y = 26.1 + 0.02X$. It is the line that minimizes the sum of the squares of the residuals (red lines).

describe the regression line: b_0 (the vertical intercept of the line, or the expected value of variable Y when $X = 0$), and b_1 (the slope of the line, or how much values of Y are expected to change with changes in values of X).

Step 5: Inferential Statistics

Data analysis often culminates with statistical inference—an attempt to draw general conclusions about the system under investigation. As depicted in Figure B1, the primary reason we collect data is to gain insight into the larger system from which the data are collected. When we test a new medulloblastoma brain cancer drug on ten patients, we do not simply want to know the fate of those ten individuals; rather, we hope to predict its efficacy on the much larger group of all medulloblastoma patients.

STATISTICAL HYPOTHESES When it comes to inferring something about the real world from our data, we often have a “*Whether or not*” question in mind. For example, we would like to know whether or not global warming impacts biodiversity; whether or not the clutch size of a spider increases with body size; or whether or not soil nitrogen increases the growth of a particular plant species.

Before making statistical inferences from data, we must formalize our “*Whether or not*” question into a pair of opposing hypotheses—a **null hypothesis** (denoted H_0) and an **alternative hypothesis** (denoted H_A). The alternative hypothesis is the “*Whether*”—it is formulated to describe the effect that we expect our data to support; the null hypothesis is the “*or not*”—it is formulated to represent the absence of the effect. In other words, we typically conduct our experiment seeking to demonstrate something new (the alternative hypothesis) and thereby reject the idea that it does not occur (the null hypothesis).

Suppose, for example, we would like to know *whether or not* a new vaccine is more effective than an existing vaccine at

immunizing children against influenza. Our hypotheses would be as follows:

- H_0 : The new vaccine is not more effective than the old vaccine.
- H_A : The new vaccine is more effective than the old vaccine.

If we would like to know whether radiation increases the mutation rate in the bacteria *Escherichia coli*, we would set up the following hypotheses:

- H_0 : Radiation does not increase the mutation rate of *E. coli*.
- H_A : Radiation does increase the mutation rate of *E. coli*.

STATISTICAL BURDEN OF PROOF In the U.S. justice system, people are innocent until proven guilty. In statistics, the world is *null until proven alternative*. Statistics requires overwhelming proof in favor of the alternative hypothesis before rejecting the null hypothesis. In other words, scientists favor existing ideas and resist adopting new ideas until compelling evidence suggests otherwise. This is based on a philosophy that it is worse to accept new claims when they are false than to miss out on discovering some true facts about world.

When testing a new influenza vaccine, the burden of proof is on the new vaccine. Suppose we were to vaccinate three children with the new vaccine (Group A), three with the old vaccine (Group B) and leave three children unvaccinated (Group C). If no children from Group A, one child from Group B, and one child from Group C became infected, would we have enough evidence to conclude that the new vaccine is superior to the old vaccine? No, we would not. If the study were enlarged, and two out of 100 children in group A, seven out of 100 children in group B, and 22 out of 100 children in group C become infected, would we then have sufficient evidence to choose the new vaccine? Perhaps, but we need to use statistics to be sure.

This is the traditional burden of proof in biology and science in general. As a consequence, scientists are more likely to miss out on discovering something new (and true) about the world than they are to make a false discovery. In recent years, scientists have begun to question this approach and develop an alternative statistical approach, called **Bayesian inference**, which makes it easier to favor new hypotheses. In this primer, we discuss only traditional statistical methods, often called **frequentist statistics**.

		The real world	
		Null hypothesis true (not more females)	Null hypothesis false (more females)
Our conclusion	Null hypothesis true (not more females)	✓	Type 2 error (false negative)
	Null hypothesis false (more females)	Type 1 error (false positive)	✓

B10 Two Types of Error Possible outcomes of a statistical test. Statistical inference can result in correct and incorrect conclusions about the population of interest.

JUMPING TO THE WRONG CONCLUSIONS There are two ways that a statistical test can go wrong (**Figure B10**). We can reject the null hypothesis when it is actually true (**Type I error**) or we can accept the null hypothesis when it is actually false (**Type II error**). These kinds of errors are analogous to false positives and false negatives in medical testing, respectively. If we mistakenly reject the null hypothesis when it is actually true, then we falsely endorse the incorrect hypothesis. If we are unable to reject the null hypothesis when it is actually false, then we fail to realize a yet undiscovered truth.

Suppose we would like to know whether there are more females than males in a population of 10,000 individuals. To determine the makeup of the population, we choose 20 individuals randomly and record their sex. Our null hypothesis is that there are *not* more females than males; and our alternative hypothesis is that there are. The following scenarios illustrate the possible mistakes we might make:

- **Scenario 1:** The population actually has 40% females and 60% males. Although our random sample of 20 people is likely to be dominated by males, it is certainly possible that, by chance, we will end up choosing more females than males. If this occurs, and we mistakenly reject the null hypothesis (that there are *not* more females than males), then we make a Type I error.
- **Scenario 2:** The population actually has 60% females and 40% males. If, by chance, we end up with a majority of males in our sample and thus fail reject the null hypothesis, then we make a Type II error.

Fortunately, statistics has been developed precisely to avoid these kinds of errors and inform us about the reliability of our conclusions. The methods are based on calculating the **probabilities** of different possible outcomes. Although you may have heard or even used the word “probability” on multiple occasions, it is important that you understand its mathematical meaning. A probability is a numerical quantity that expresses the likelihood of some event. It ranges between zero and one; zero means that there is no chance the event will occur and one means that the event is guaranteed to occur. This only makes sense if there is an element of chance, that is, if it is possible the event will occur and possible that it will not occur. For example, when we flip a fair coin, it will land on heads with probability 0.5 and land on tails with probability 0.5. When we select individuals randomly from a population with 60% females and 40% males, we will encounter a female with probability 0.6 and a male with probability 0.4.

Probability plays a very important role in statistics. To draw conclusions about the real world (the population) from our sample, we first calculate the probability of obtaining our sample if the null hypothesis is true. Specifically, statistical inference is based on answering the following question:

Suppose the null hypothesis is true. What is the probability that a random sample would, by chance, differ from the null hypothesis as much as our sample differs from the null hypothesis?

If our sample is highly improbable under the null hypothesis, then we rule it out in favor of our alternative hypothesis. If,

instead, our sample has a reasonable probability of occurring under the null hypothesis, then we conclude that our data are consistent with the null hypothesis and we do not reject it.

Returning to the sex ratio example, we consider two new scenarios:

- **Scenario 3:** Suppose we want to infer whether or not females constitute the majority of the population (our alternative hypothesis) based on a random sample containing 12 females and eight males. We would calculate the probability that a random sample of 20 people includes at least 12 females assuming that the population, in fact, has a 50:50 sex ratio (our null hypothesis). This probability is 0.13, which is too high to rule out the null hypothesis.
- **Scenario 4:** Suppose now that our sample contains 17 females and three males. If our population is truly evenly divided, then this sample is much less likely than the sample in scenario 3. The probability of such an extreme sample is 0.0002, and would lead us to rule out the null hypothesis and conclude that there are more females than males.

This agrees with our intuition. When choosing 20 people randomly from an evenly divided population, we would be surprised if almost all of them were female, but would not be surprised at all if we ended up with a few more females than males (or a few more males than females). Exactly how many females do we need in our sample before we can confidently infer that they make up the majority of the population? And how confident are we when we reach that conclusion? Statistics allows us to answer these questions precisely.

STATISTICAL SIGNIFICANCE: AVOIDING FALSE POSITIVES Whenever we test hypotheses, we calculate the probability just discussed, and refer to this value as the **P-value** of our test. Specifically, the *P*-value is the probability of getting data as extreme as our data (just by chance) if the null hypothesis is, in fact, true. In other words, it is the likelihood that chance alone would produce data that differ from the null hypothesis as much as our data differ from the null hypothesis. How we measure the difference between our data and the null hypothesis depends on the kind of data in our sample (categorical or quantitative) and the nature of the null hypothesis (assertions about proportions, single variables, multiple variables, differences between variables, correlations between variables, etc.).

For many statistical tests, *P*-values can be calculated mathematically. One option is to quantify the extent to which the data depart from the null hypothesis and then use look-up tables (available in most statistics textbooks, or on the internet) to find the probability that chance alone would produce a difference of that magnitude. Most scientists, however, find *P*-values primarily by using statistical software rather than hand calculations combined with look-up tables. Regardless of the technology, the most important steps of the statistical analysis are still left to the researcher: constructing appropriate null and alternative hypotheses, choosing the correct statistical test, and drawing correct conclusions.

After we calculate a *P*-value from our data, we have to decide whether it is small enough to conclude that our data are inconsistent with the null hypothesis. This is decided by comparing

the *P*-value to a threshold called the **significance level**, which is often chosen even before making any calculations. We reject the null hypothesis only when the *P*-value is less than or equal to the significance level, denoted α . This ensures that, if the null hypothesis is true, we have at most a probability α of accidentally rejecting it. Therefore, the lower the value of α , the less likely you are to make a Type I error (lower left cell of Figure B10). The most commonly used significance level is $\alpha = 0.05$, which limits the probability of a Type I error to 5%.

If our statistical test yields a *P*-value that is less than our significance level α , then we conclude that the effect described by our alternative hypothesis is statistically significant at the level α and we reject the null hypothesis. If our *P*-value is greater than α , then we conclude that we are unable to reject the null hypothesis. In this case, we do not actually reject the alternative hypothesis, rather we conclude that we do not yet have enough evidence to support it.

POWER: AVOIDING FALSE NEGATIVES The **power** of a statistical test is the probability that we will correctly reject the null hypothesis when it is false (lower right cell of Figure B10). Therefore, the higher the power of the test, the less likely we are to make a Type II error (upper right cell of Figure B10). The power of a test can be calculated, and such calculations can be used to improve your methodology. Generally, there are several steps that can be taken to increase power and thereby avoid false negatives:

- **Decrease the significance level, α .** The higher the value of α , the harder it is to reject the null hypothesis, even if it is actually false.
- **Increase the sample size.** The more data one has, the more likely one is to find evidence against the null hypothesis, if it is actually false.
- **Decrease variability in the sample.** The more variation there is in the sample, the harder it is to discern a clear effect (the alternative hypothesis) when it actually exists.

It is always a good idea to design your experiment to reduce any variability that may obscure the pattern you seek to detect. For example, it is possible that the chance of a child contracting influenza varies depending on whether he or she lives in a crowded (e.g., urban) environment or one that is less so (e.g., rural). To reduce variability, a scientist might choose to test a new influenza vaccine only on children from one environment or the other. After you have minimized such extraneous variation, you can use power calculations to choose the right combination of α and sample size to reduce the risks of Type I and Type II errors to desirable levels.

There is a trade-off between Type I and Type II errors: As α increases, the risk of a Type I decreases but the risk of a Type II error increases. As discussed above, scientists tend to be more concerned about Type I errors than Type II errors. That is, they believe that it is worse to mistakenly believe a false hypothesis than it is to fail to make a new discovery. Thus, they prefer to use low values of α . However, there are many real-world scenarios in which it would be worse to make a Type II error than a Type I error. For example, suppose a new cold medication is

being tested for dangerous (life-threatening) side effects. The null hypothesis is that there are no such side effects. A Type II error might lead regulatory agencies to approve a harmful medication that could cost human lives. In contrast, a Type I error would simply mean one less cold medication among the many that already line pharmacy shelves. In such cases, policymakers take steps to avoid a Type II error, even if, in doing so, they increase the risk of a Type I error.

STATISTICAL INFERENCE WITH QUANTITATIVE DATA There are many forms of statistical inference for quantitative data. When measuring a single quantitative variable, like birth weight in lambs, calcium concentration in the blood of pregnant women, or migration rate of birds, we often wish to infer the mean value of the population from which we drew the sample. However, the mean of a randomly chosen sample will not necessarily be the same or even close to the population mean. Suppose we wanted to know the average weight of newborn lambs on a particular farm. By chance, we may end up with a random sample that includes an excess of lightweight lambs and therefore a sample mean that is less than the overall mean in the population.

To infer the population mean from the sample data, we can calculate a **confidence interval for the mean**. This is a statistically derived range of values that is centered on the sample mean and is likely to include the population mean. For example, based on the sample of 34 *Abramis brama* weights from Lake Laengelmavesi (see Table B2; Figure B4), the 95% confidence interval for the mean weight ranges from 554 grams to 698 grams. The true average weight for this species of fish is likely, but not guaranteed, to fall within this range.

RESEARCHTOOLS

B11 The t-Test

What is the t-test? It is a standard method for assessing whether the means of two groups are statistically different from each another.

Step 1: State the null and alternative hypotheses:

H_0 : The two populations have the same mean.

H_A : The two populations have different means.

Step 2: Choose a significance level, α , to limit the risk of a Type 1 error.

Step 3: Calculate the test statistic: $t_s = \frac{\bar{y}_1 - \bar{y}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}}$

Notation: \bar{y}_1 and \bar{y}_2 are the sample means; s_1 and s_2 are the sample standard deviations; and n_1 and n_2 are the sample sizes.

Step 4: Use the test statistic to assess whether the data are consistent with the null hypothesis:

Calculate the *P-value* (P) using statistical software or by hand using statistical tables.

Step 5: Draw conclusions from the test:

If $P \leq \alpha$, then reject H_0 , and conclude that the population distribution is significantly different.

If $P > \alpha$, then we do not have sufficient evidence to conclude that the means differ.

Biologists frequently wish to compare the mean values in two or more groups; for example, newborn lamb weights on several different farms, calcium concentration in women in early and late stages of pregnancy, or migration rates in birds of different species. Based on the means and standard deviations calculated for each of the samples, they infer whether or not the means in the different populations are statistically different from one another. There are several statistical methods for this, and the correct method depends on the number of groups, the experimental design, and the nature of the data.

Figure B11 describes the steps of a *t*-test, a simple method for comparing the means in two different groups. To illustrate, we can apply a *t*-test to the Lake Laengelmavesi data to assess whether the two fish species *Abramis brama* and *Leusiscus idus* have significantly different mean weights. We begin by stating our hypotheses and choosing a significance level:

H_0 : *Abramis brama* and *Leusiscus idus* have the same mean weight.

H_A : *Abramis brama* and *Leusiscus idus* have different mean weights.

$\alpha = 0.05$

The test statistic is calculated using the means, standard deviations, and sizes of the two samples:

$$t_s = \frac{626 - 531}{\sqrt{\frac{207^2}{34} + \frac{310^2}{6}}} = 0.724$$

We can use statistical software or one of the free statistical sites on the internet to find the *P*-value for this result to be $P = 0.497$. Since P is considerably greater than α , we fail to reject the null hypothesis and conclude that our study does not provide evidence that the two species have different mean weights.

You may want to consult an introductory statistics textbook to learn more about confidence intervals, *t*-tests, and other basic statistical tests.

STATISTICAL INFERENCE WITH CATEGORICAL DATA With categorical data, we often wish to infer the distribution of the different categories within the populations from which our samples are drawn. In the simplest case, we have a single categorical variable with two or more categories. If there are just two categories, we can construct a **confidence interval for the proportion** of the population that belongs to one of the two categories. This is a statistically derived range of values that is centered on the sample proportion and is likely to include the population proportion. If there are three or more categories, we can use a **chi-square goodness-of-fit** test to determine whether the distribution of the different categories in the population is consistent with a specific distribution.

Figure B12 outlines the steps of a chi-square goodness-of-fit-test. As an example, consider the data described in Table B1. Many plant species have simple Mendelian genetic systems in which parent plants produce progeny with three different colors of flowers in a ratio of 2:1:1. However, a botanist believes that these particular poinsettia plants have a different genetic system that does not produce a 2:1:1 ratio of red, pink, and

RESEARCH TOOLS

B12 The Chi-Square Goodness-of-Fit Test

What is the chi-square goodness-of-fit test? It is a standard method for assessing whether a sample came from a population with a specific distribution.

Step 1: State the null and alternative hypotheses:

H_0 : The population has the specified distribution.

H_A : The population does not have the specified distribution.

Step 2: Choose a significance level, α , to limit the risk of a Type 1 error.

Step 3: Determine the observed frequency and expected frequency for each category:

The observed frequency of a category is simply the number of observations in the sample of that type.

The expected frequency of a category is the probability of the category specified in H_0 multiplied by the overall sample size.

Step 4: Calculate the test statistic: $\chi_s^2 = \sum_{i=1}^c \frac{(O_i - E_i)^2}{E_i}$

Notation: C is the total number of categories, O_i is the observed frequency of category i , and E_i is the expected frequency of category i .

Step 5: Use the test statistic to assess whether the data are consistent with the null hypothesis:
Calculate the P -value (P) using statistical software or by hand using statistical tables.

Step 6: Draw conclusions from the test:

If $P \leq \alpha$, then reject H_0 , and conclude that the population distribution is significantly different than the distribution specified by H_0 .

If $P > \alpha$, then we do not have sufficient evidence to conclude that population has a different distribution.

white plants. A chi-square goodness-of-fit can be used to assess whether or not the data are consistent with this ratio, and thus whether or not this simple genetic explanation is valid. We start by stating our hypotheses and significance level:

H_0 : The progeny of this type of cross have the following probabilities of each flower color:

$\Pr\{\text{Red}\} = .50$, $\Pr\{\text{Pink}\} = .25$, $\Pr\{\text{White}\} = .25$

H_A : At least one of the probabilities of H_0 is incorrect.

$\alpha = 0.05$

We next use the probabilities in H_0 and the sample size to calculate the expected frequencies:

	Red	Pink	White
Observed	108	34	40
Expected	$(.50)(182) = 91$	$(.25)(182) = 45.5$	$(.25)(182) = 45.5$

Based on these quantities, we calculate the chi-square test statistic:

$$\chi_s^2 = \sum_{i=1}^c \frac{(O_i - E_i)^2}{E_i} = \frac{(108 - 91)^2}{91} + \frac{(34 - 45.5)^2}{45.5} + \frac{(40 - 45.5)^2}{45.5} = 6.747$$

We find the P -value for this result to be $P = 0.0343$ using statistical software. Since P is less than α , we reject the null hypothesis and conclude that the botanist is correct: The plant color patterns cannot be explained by the simple Mendelian genetic model under consideration.

This introduction is only meant to provide a brief introduction to the concepts of statistical analysis, with a few example tests. **Figure B13** provides a summary of some of the commonly used statistical tests that you may encounter in biological studies.

**B13 Some Common Methods of Statistical Inference**

This flow chart shows some of the commonly used methods of statistical inference for different combinations of data. Detailed descriptions of these methods can be found in most introductory biostatistics textbooks.

Appendix C

Some Measurements Used in Biology

MEASURES OF	UNIT	EQUIVALENTS	METRIC → ENGLISH CONVERSION
Length	meter (m)	base unit	1 m = 39.37 inches = 3.28 feet = 1.196 yards
	kilometer (km)	1 km = 1000 (10 ³) m	1 km = 0.62 miles
	centimeter (cm)	1 cm = 0.01 (10 ⁻²) m	1 cm = 0.39 inches
	millimeter (mm)	1 mm = 0.1 cm = 10 ⁻³ m	1 mm = 0.039 inches
	micrometer (μm)	1 μm = 0.001 mm = 10 ⁻⁶ m	
	nanometer (nm)	1 nm = 0.001 μm = 10 ⁻⁹ m	
Area	square meter (m ²)	base unit	1 m ² = 1.196 square yards
	hectare (ha)	1 ha = 10,000 m ²	1 ha = 2.47 acres
Volume	liter (L)	base unit	1 L = 1.06 quarts
	milliliter (mL)	1 mL = 0.001 L = 10 ⁻³ L	1 mL = 0.034 fluid ounces
	microliter (μL)	1 μL = 0.001 mL = 10 ⁻⁶ L	
Mass	gram (g)	base unit	1 g = 0.035 ounces
	kilogram (kg)	1 kg = 1000 g	1 kg = 2.20 pounds
	metric ton (mt)	1 mt = 1000 kg	1 mt = 2,200 pounds = 1.10 ton
	milligram (mg)	1 mg = 0.001 g = 10 ⁻³ g	
	microgram (μg)	1 μg = 0.001 mg = 10 ⁻⁶ g	
Temperature	degree Celsius (°C)	base unit	°C = (°F – 32)/1.8 0°C = 32°F (water freezes) 100°C = 212°F (water boils) 20°C = 68°F (“room temperature”) 37°C = 98.6°F (human internal body temperature)
	Kelvin (K)*	K = °C – 273	0 K = –460°F
Energy	joule (J)		1 J ≈ 0.24 calorie = 0.00024 kilocalorie [†]

*0 K (–273°C) is “absolute zero,” a temperature at which molecular oscillations approach 0—that is, the point at which motion all but stops.

[†]A *calorie* is the amount of heat necessary to raise the temperature of 1 gram of water 1°C. The *kilocalorie*, or nutritionist’s calorie, is what we commonly think of as a calorie in terms of food.

Answers to Chapter Review Questions

CHAPTER 1

1. e 2. b 3. e 4. d 5. e

6. In science, we formulate hypotheses about how the world works, then try to reject those hypotheses with experiments. The experiments must be designed so that we would expect them to uncover problems with our hypothesis. If the experiments are incapable of rejecting a hypothesis, then the experiments are not a rigorous test of the hypothesis.
7. The independent DNA found in mitochondria and chloroplasts is evidence of the origin of these eukaryotic organelles from ancient bacteria that became incorporated in the eukaryotic cell. Since the ancestors of these organelles once existed as independent organisms, they have their own genomes.
8. Controlled experiments, by definition, are able to control many variables in carefully maintained experiments, often in laboratory conditions. Comparative experiments, in contrast, often contain many additional variables that cannot be controlled by the investigator. Comparative experiments often incorporate realistic variation from uncontrolled factors, which accounts for their higher overall variability.
9. If two species share particular changes in the gene we compare, and those changes are not shared by other species we examine, we would expect the two species with the common changes to be more closely related to one another. By comparing many such changes in many genes, we can group species based on their relative evolutionary divergence from one another. For example, we share more changes in our genes with chimpanzees than we do with gorillas. From this, we can deduce that humans and chimpanzees shared a more recent common ancestor than they shared with gorillas.
10. Mitochondrial DNA is often used to follow the history of maternal lineages in a population or species. Nuclear DNA is not used in such cases because it is typically inherited from both parents. This difference can be useful in many circumstances. For example, we might examine a hybrid individual between two species. Equal portions of nuclear DNA from both species could confirm that the individual is a direct hybrid between the two species. If we examine the mitochondrial DNA, however, we can learn which of the two parental species was the female in the cross—and therefore learn by default which was the male.

CHAPTER 2

1. b 2. d 3. c 4. c 5. a 6. d

7.

8. An easy way to answer this question is to make a simple table:

	Covalent H—H	Hydrogen H·····O
Electrons	Shared	Remain with H and O
Polarity	Nonpolar	Polar; + at H end
Strength	Stronger	Weaker

9. C—H: nonpolar; hydrophobic
C=O: polar; δ- at O; hydrophilic
O—P: polar; δ- at O; hydrophilic
C—C: nonpolar; hydrophobic

10. This is an example of Van der Waals forces, which act over a short distance and do not involve polarity.
11. The human body has the same elements as Earth's crust but in very different proportions.

CHAPTER 3

1. e 2. e 3. c 4. a 5. c 6. b

7. The observations support explanation "a." Glycine is small and nonpolar. Glutamic acid and arginine are larger and polar (charged). Serine and alanine are small: the protein retains its shape. But serine is polar (it has -OH as its R group), and that does not affect the structure. Valine is larger and nonpolar, and this affects shape. So the issue is size.
8. Mannose and galactose have the same atomic formula, $C_6H_{12}O_6$, but the arrangement of atoms is different: compare carbons 2 and 4. These sugars have the hydroxyl (-OH) functional group. Its polarity helps the sugars dissolve in water. The -OH group also can participate in bonding the sugar to other molecules through condensation reactions (see Figures 3.4 and 3.17).
9. High temperature disrupts weak interactions such as hydrogen bonds. Heat shock proteins might work by stabilizing the protein so that the weak interactions are not necessary to preserve its structure.
10. A change from lysine is a change in primary structure. The change could affect tertiary structure if the protein folds as a result of electrostatic attractions between charged amino acids (+ to -). In this case, the presence of a negatively charged amino acid (aspartic acid) where there should be a positively charged one (lysine) might prevent correct folding if a negatively charged amino acid elsewhere in the polypeptide chain is involved in folding (it is attracted to a + amino acid). The same forces might be at work in the interaction of separate chains for quaternary structure.
11. See Figure 3.10. Heat breaks hydrogen bonds and other weak interactions that maintain protein shape. Disulfide bonds also required for normal protein shape. Styling and perms partially denature keratin, then renature the protein in a new shape. Your investigation might involve measuring keratin protein structure of hair before and after disrupting hydrogen bonds and disulfide bonds.

CHAPTER 4

1. c 2. c 3. c 4. c 5. b 6. b

7. The presence of O_2 in the atmosphere produces an oxidizing condition that prevents the reduction reactions noted by the Miller-Urey experiment.
8. Oligonucleotides of RNA can fold because of hydrogen bonds forming between bases on the single chain and to a lesser extent because of weak interactions of base stacking when bases come near one another. Short strands of about 20 oligonucleotides are enough to produce uniquely folded RNA.
9. Cells provided concentration and compartmentation chemicals for the reactions needed for life, as well as differential permeability to distinguish life's chemical composition from that of the environment.
10. If microbes survived heat, the initial part of Pasteur's experiment might begin with microbes already present. They would grow in both the open and closed flasks. To get the results he did, Pasteur's flasks must not have contained such microbes. An answer for the proposed experiment on heat-stable microbes might be to inactivate them using reagents, such as mercaptoethanol, that destroy proteins.
11. A suggested experiment might be to dry the samples after the Miller-Urey experiment (allowing condensation reactions—polymerization) and then apply energy in the form of heat. This condition might have existed in volcanic rock in early Earth.

CHAPTER 5

1. b 2. d 3. e 4. a 5. d 6. b 7. a

8. Four membranes: two in the chloroplast and two in the mitochondrion
Two membranes: the lysosomal membrane and the plasma membrane (via vesicle; the molecules do not themselves cross any membranes)

A-2 Answers to Chapter Review Questions

No membranes: ribosomes do not have membranes. However, if the ribosomes were associated with the endoplasmic reticulum (ER), the answer would be two membranes: into the ER and out of the ER.

9.

	Animal Cell ECM	Plant Cell Wall
Composition	Collagen fibers in proteoglycan matrix	Cellulose fibers in polysaccharide and protein matrix
Rigidity	Less rigid	More rigid (especially secondary cell walls)
Connections	Some specialized proteins and junctions	Plasmodesmata

10. Microtubules line the long axons of nerve cells, where they act as tracks for vesicles that carry substances down the neuron. Without microtubules, the contents of these vesicles cannot be delivered to their destination, which can result in nerve problems.

Microtubules are a key part of the mitotic spindle, which is used to move chromosomes during cell division. Depolymerization of microtubules can thus result in loss of dividing cells.

11. For a lysosomal enzyme, the pathway would be ribosome → interior of ER → Golgi → Golgi vesicles → lysosome.

For an extracellular protein (animal cells), the pathway would be ribosome → interior of ER → Golgi → Golgi vesicles → plasma membrane → extracellular region.

CHAPTER 6

1. c 2. a 3. d 4. c 5. b 6. e 7. c

8. The pumping of Ca^{2+} requires a lipid bilayer membrane to separate compartments, a protein pump in the membrane, and ATP to provide energy for pumping.
9. Diatom wall components move from the Golgi apparatus to the cell wall by exocytosis.
10. Living in a hypotonic environment (cells hypertonic) results in a tendency for water to enter the organism by osmosis, which can cause swelling and dilute cell contents. Some organisms get around this by using reverse pinocytosis (exocytosis) to remove fluid.

11. Experiments might involve the following:

To measure membrane fluidity, label a small amount of a lipid or protein with a dye and allow it to incorporate into a cell's membrane. This may make a localized labeled spot on the cell. The localized region will be seen to diffuse over the cell over time. In the cancer cells, this rate of diffusion may be faster.

To measure cell adhesion, dissociate cancer and normal tissue cells. Incubate for a period of time and determine the rate at which cancer cells and normal lung cells bind to cells from the other tissues besides lung. The cancer cells may bind to a greater extent than normal cells.

CHAPTER 7

1. d 2. c 3. d 4. a 5. d 6. a 7. d 8. c

9. Different cells can have different target molecules to which cAMP binds, and these target molecules can have different activities and functions. Binding of cAMP changes the structure (e.g., tertiary structure of a protein) and therefore the function of a target molecule. So cAMP can have many effects.
10. Characteristics of direct communication: the size of signal molecules is limited by the size of openings between cells, it is not specific, it is fast, and there can be cytoplasmic connection between cells.

Characteristics of receptor-mediated communication: the signal molecules can be larger, it is specific, it is slower, and there is no direct cytoplasmic connection.

Direct communication is useful for a rapid, coordinated response of many cells.

11. See Figure 7.10. A mutation of the *Raf* gene that activates cell division might involve a protein product that does not need binding of Ras to be active. Cell division would occur without activated Ras, thereby eliminating the need for growth factor binding.

A mutation of the *MAP kinase* gene would stimulate cell division if the resulting MAP kinase protein did not need to be phosphorylated by MEK to be active. No signaling cascade would be needed for the mutant protein to enter the nucleus and stimulate cell division.

12. Experiments might involve applying a solution containing the antibody to the upper part of the *Hydra* body. The antibody would block diffusion of the signal molecule from the apex to the upper body and—if the hypothesis is correct—would allow a bud to form in the upper body. A sham experiment, in which

the solution without antibody is applied, would be a control. In this case, a bud would not form in the upper body.

CHAPTER 8

1. c 2. e 3. c 4. c 5. d 6. d

7. Endergonic reactions are coupled in time and space with exergonic reactions, which release the energy needed for the endergonic reactions.

8. A cytoplasmic enzyme generally has a globular structure with a hydrophilic exterior and an active site for substrate binding. An ion channel generally has a more linear structure with a hydrophobic membrane-spanning region and no active site.

9.

10. (a) The presence of water may prevent O_2 from reaching the enzyme. (b) Boiling denatures proteins, so polyphenol oxidase is irreversibly altered by boiling and its active site is destroyed. (c) Proteins have an optimal pH at which ionized R groups are appropriately charged to give the protein its tertiary structure. A pH 3 of may not be that optimal pH for polyphenol oxidase, so the enzyme is denatured and inactive.

11. See Figure 8.17. A competitive inhibitor binds to the active site of the enzyme and shifts the equilibrium to enzyme molecules in the active form.

12. To determine whether catalase has an allosteric or nonallosteric mechanism, perform an experiment with varying amounts of substrate and plot rate of catalase versus substrate concentration. An S-shaped curve will indicate an allosteric mechanism. A hyperbolic curve indicates a nonallosteric enzyme.

To determine if a pollutant is a competitive or noncompetitive inhibitor, add the pollutant to the catalase to lower the rate of reaction, then add increasing amounts of substrate. A competitive inhibitor will be removed from the active site and the rate of reaction will increase. A noncompetitive inhibitor will not allow the rate to increase as more substrate is added. (There are more sophisticated kinetic experiments that you will learn in a biochemistry course).

CHAPTER 9

1. d 2. d 3. e 4. c 5. d 6. a

7. If cytochrome *c* remains reduced and cannot accept electrons, the electron transport (respiratory) chain stays reduced and NADH and FADH_2 remain reduced. This prevents oxidation reactions in the citric acid cycle and pyruvate oxidation, so pyruvate cannot be converted to acetyl CoA. Instead, pyruvate is converted to lactic acid, regenerating some NAD that can be used so that glycolysis can continue. Because the electron transport chain is not working, there is no proton gradient set up in the mitochondria, and ATP is not made by oxidative phosphorylation.

8. See Figure 9.13. Some amino acids are converted to intermediates of glycolysis. Once they enter glycolysis these intermediates are further metabolized to a

glycolytic intermediate that can be converted to glycerol, which is incorporated into triglycerides. Glycolysis and pyruvate oxidation produce acetyl CoA, which is converted to fatty acids and incorporated into lipids.

Glucose is converted in glycolysis to acetyl CoA, which is then converted to fatty acids as above.

9. (a) Oxidation (removal of H from C2 and C3 of succinate)
(b) Exergonic (because it is an oxidation)
(c) It requires the redox coenzyme NAD or FAD.
(d) The fumarate is converted to other intermediates that regenerate oxaloacetate, the acceptor for the citric acid cycle.
(e) The reduced coenzyme (NADH or FADH₂) is reoxidized in the electron transport chain.
10. Anaerobes use alternate electron acceptors to generate energy, such as sulfur, sulfate, and nitrate. Also, they use substrate-level phosphorylation (direct transfer of phosphate to ADP) to make ATP.
11. The proton gradient in the experiment described in Figure 9.9 was generated artificially from the solution and did not require electron transport (a respiratory chain). The presence of antimycin A thus would have no effect on the experiment.

CHAPTER 10

1. e 2. b 3. d 4. d 5. d 6. d

7. In the dark, photosynthetic electron transport stops at photosystem II → reduced PQ (plastoquinone). Initially, the chlorophylls in light-harvesting complexes remain reduced, so reaction-center chlorophylls remain reduced and thus photosystem II remains reduced.

In the dark, the Calvin cycle stops at the reduction phase, which requires NADH. No RuBP is regenerated, so there is no rubisco activity. The initial reactions are no oxidation of photosystem I, and no reduction of NADP to NADPH.

8. These processes can be compared using a table:

	Cyclic Electron Transport	Noncyclic Electron Transport
Products	ATP	ATP, NADPH, O ₂
Source of electrons	Electron transport	Electron transport (photosystem I) or water (photosystem II)

9. See Figure 10.18. CO₂ carbons end up in 3PG, which is converted to pyruvate. Pyruvate goes to the citric acid cycle, where some of the intermediates are converted to amino acids, which are incorporated into protein.
In the Calvin cycle, some 3PG is converted to G3P, which can enter glycolysis. Some of the intermediates of glycolysis are converted to amino acids, which are incorporated into protein.
10. (a) O₂
(b) NADPH
(c) 3PG
11. (a) Here is the pathway followed by ¹⁴C: ¹⁴CO₂ → cells → photosynthesis → carbohydrate → combustion → ¹⁴CO₂. Release of ¹⁴CO₂ upon combustion would be evidence of photosynthesis (and life).
(b) In this case: ¹⁴CO₂ → heat denatured cells, no photosynthesis. If living things were present, ¹⁴CO₂ would be released in experiment (a), but not in experiment (b).

CHAPTER 11

1. d 2. b 3. d 4. d 5. e 6. d 7. d 8. c

9. See Figure 11.19. In mitotic prophase, there is no pairing of homologous chromosomes, and crossing over is rare. In meiotic prophase I, homologous pairs of chromosomes align, and crossing over is common.
In mitotic anaphase, sister chromatids separate, with one going to each pole. In meiotic anaphase I, sister chromatids do not separate; homologous pairs of chromosomes separate, with one pair going to each pole.
10. Normally, p53 induces expression of p21, which binds to the G1/S Cdk and prevents cyclin from activating it. Without active Cdk, the cell cycle ceases. If p53 is mutated such that it is nonfunctional, p21 is not induced and the cyclin-Cdk complex can form and stimulate the cell cycle at S phase.
11. Cancers often have multiple mutations in different cells of the tumor. If some of these mutations affect different parts of the cell cycle, targeting the different phases may be a useful therapy.
12. Your proposed experiments should involve isolating the synchronous meiotic cells from the lily anthers and establishing them in the lab. As the cells proceed

through the meiotic cell cycle they can be analyzed at different stages for the presence and biochemical activity of various cyclins and Cdks.

CHAPTER 12

1. e 2. a 3. d 4. d 5. d 6. b 7. b 8. d 9. b
10. $BB \times bb; bb \times bb; Bb \times bb; Bb \times Bb$
 11. 1/32
 12. (a) Autosomal dominant
(b) 1/4
 13. (a) Males (XY) contain only one allele and will show only one color, black ($X^B Y$) or yellow ($X^b Y$). Females can be heterozygous ($X^B X^b$).
(b) $X^b Y$, yellow
 14. The body color (G/g) and wing size (A/a) genes are linked; eye color (R/r) is unlinked to the other two genes. The distance between the linked genes is 18.5 units.
 15. Yellow, blue, and white in a 1:2:1 ratio.
 16. F₁ will all be wild type, $PpSsws$. F₂ will have phenotypes in the ratio 9:3:3:1; see Figure 12.6 (p. 238) for analogous genotypes.
 17. (a) F₁ will all be $PpByby$ and will have wild-type eye color and wings. The ratio of phenotypes in F₂ will be 3:1, $PPByBy$ (wild-type eyes and wings) to $ppbyby$ (pink eyes and blistery wings).
(b) F₁ will all be $PpyByy$ with wild-type eye color and wings; they will produce just two kinds of gametes (Pby and pBy). Combine them carefully and see the 1:2:1 phenotypic ratio fall out in the F₂: 1 wild-type eyes/blistery wings : 2 wild-type eyes/wild-type wings : 1 pink eyes/wild-type wings.
(c) Pink-blistery
(d) See Figures 11.16 and 11.18 (pp. 220–222). Crossing over took place in F₁.
 18. $Rraa$ and $RrAa$
 19. (a) $w^+ > w^e > w$
(b) The parents are $w^e w$ and $w^+ Y$. The progeny are $w^+ w^e$, $w^+ w$, $w^e Y$, and $w Y$.
 20. (a) BX^a , BY , bX^a , bY
(b) The mother is $bbX^A X^a$, the father $BbX^a Y$, the son $BbX^a Y$, and the daughter $bbX^a X^a$.
 21. 75 percent
 22. Because the gene is carried on mitochondrial DNA, it is passed through the mother only. Thus if the women does not have the disease but her husband does, their child will not be affected. However, if the woman has the disease but her husband does not, their child will have the disease.
 23. The cross $RRYY \times rryy$ produces $RrYy$ (round, yellow) F₁ offspring. If the seed shape and seed color genes were linked with no recombination between them, the F₂ would also be all $RrYy$. A distance of 10 map units between two genes means that on average 10% of the F₂ offspring will have recombinant phenotypes, in this case round green (5%) and wrinkled yellow (5%).
The cross in Figure 12.19 is $BbVgvg$ (gray, normal) \times $bbvgvg$ (black, vestigial). If there were no linkage between the genes, then the gray, normal parent would produce four types of gametes: BVg , bVg , Bvg , and bvg . When these combine with the bvg gametes produced by the other parent, four types of offspring in a 1:1:1:1 ratio will result: $BbVgvg$ (gray, normal), $bbVgvg$ (black, normal), $Bbvgvg$ (gray, vestigial), and $bbvgvg$ (black, vestigial).

CHAPTER 13

1. a 2. c 3. b 4. b 5. d 6. c 7. d
8. At 3,000 bp per minute in two directions, each origin grows at 6,000 bp per minute. There are 300 minutes in S phase, so the total bp possible for one origin is $(300 \times 6,000) = 1,800,000$. If there are 120 million bp to replicate, then the total number of origins is 120 million/1.8 million = 66 origins. If there are 3 μm of DNA, this means there are about 22 origins per micrometer of DNA.
 9. DNA replication adds new nucleotides to the 3' end of DNA, where there is an —OH group on the sugar at the 3' position. If there is no —OH group, there cannot be a condensation reaction and formation of a bond to the next nucleotide, so replication stops.
 10. After ten rounds there would still have been some DNA (about 1/512th) as hybrid because the original heavy DNA template strands would still have been there. This tiny amount might not have been detectable in the centrifuge, however.
 11. The proposed experiments might use S strain pneumococcus and transform R strain as in Figure 13.1. Incubate separate batches of S strain bacteria in ³²P or ³⁵S. Make cell-free extracts of the S strains. Incubate with R cells and look for their transformation to the S phenotype. Then check to see if there is ³²P or ³⁵S label in the newly transformed cells. It would be expected that only ³²P label (DNA) would enter the cells.

CHAPTER 14

1. b 2. a 3. d 4. b 5. d 6. d 7. d 8. e
9. For 192 amino acids, the triplet genetic code mandates 576 bp of coding sequence. Add the start and stop codons and the total is 582. This is shorter than the actual DNA gene because of promoter and terminator of transcription sequences; introns; and ribosome binding sequences. All except the transcription signals are transcribed into the pre-mRNA. The mature mRNA has the introns removed.
10. Errors in transcription can be tolerated because many copies of each RNA are made; if a few have errors, there are enough perfect ones to overcome any problem. Errors in DNA replication are harmful because DNA is replicated only once in the life of the cell.
11. In the poly CA experiment, threonine is ACA or CAC and histidine is ACA or CAC. In the poly CAA experiment, threonine is CAA, ACA, or AAC. Therefore in the first experiment threonine must be ACA and histidine CAC.
12. Enzymes: 4 → 2 → 3 → 1 → 5
Compounds: C → F → E → D → G → T

CHAPTER 15

1. a 2. c 3. b 4. b 5. d 6. b
7. (a) In a loss of function mutation, a phenotype is not present; for example, there may be a loss of enzyme activity. In a gain of function mutation, a new phenotype is present; for example, a new signaling protein may be active.
- (b) In a missense mutation, a single base pair change results in a codon change and thus an amino acid change in a protein. In a nonsense mutation, a single base pair change results in a codon change to a stop codon and thus premature termination of a protein.
- (c) In a spontaneous mutation, DNA changes as a result of unprovoked chemical changes or replication errors. In an induced mutation, DNA changes as a result of outside physical or chemical agents.
8. (a) The mutation that leads to PKU is rare in the human population; most people do not have the harmful allele and the highest probability is that the father is homozygous normal. Because the mother has PKU (she is homozygous mutant), the developing fetus is heterozygous.
- (b) High levels of phenylalanine cause brain damage. If the mother's phenylalanine levels were too high, the baby would be born with brain problems.
- (c) The woman should be on a phenylalanine-restricted diet.
9. Testing for the cystic fibrosis (CF) allele could be done by allele-specific oligonucleotide hybridization with probes for the normal and CF alleles; see Figure 15.18. Or direct DNA sequencing of the CF gene could be done. A person who is a carrier will test positive for both the normal and the mutant alleles.
- To do gene therapy, the normal allele for CF could be inserted into a viral vector that can infect cells in the lung and airway tissues. Then the virus could be sprayed onto these tissues.
10. Early identification of people with multifactorial diseases, even before symptoms appear, could lead to therapeutic interventions to prevent disease development. Ethical issues might include insurability, hiring eligibility, and social stigma.
11. An enzyme test for HEXA would reveal intermediate levels in people who are carriers. This could be done on accessible cells (e.g., blood) if the gene is expressed there. A DNA test could involve sequencing the gene by allele-specific oligonucleotide hybridization (see the answer to Question 9). The advantage of DNA testing is that it can be done on any cells from the body (not just cells that express the enzyme).
- Investigation of the stop codon hypothesis would involve isolating the HEXA protein from patients with Tay-Sachs disease and showing that it is shorter in primary structure than the protein encoded by the normal allele.
12. (a) The amino acid sequence would be Leu-Ile-Ser-Ile-Ala. This is a missense mutation.
- (b) The mutation replaces proline with serine. Proline is a nonpolar amino acid that is usually part of bends or loops in a protein; serine is a polar amino acid with a smaller side chain. The mutation is likely to affect enzyme activity because it is likely to affect protein structure.
- (c) See p. 317. This region of the gene could be amplified by PCR and then digested with *EcoRV*. The mutant DNA will be cut, but the wild-type DNA won't be.

CHAPTER 16

1. b 2. a 3. e 4. b 5. c 6. d

7. The easiest way to answer this question is to construct a simple table:

	Lysogenic Bacteriophage	HIV
(a) Viral entry to host cell	Attachment of viral protein to host cell membrane	Membrane fusion of virus to host cell membrane
(b) Virus release from host	Host cell lysis	Budding and exocytotic release
(c) Viral genome replication	Host DNA polymerase	Virus reverse transcriptase followed by host RNA polymerase
(d) New virus production	Host transcription of virus genes and host-mediated translation of virus proteins	Same as in lysogenic bacteria

8. In a prokaryotic gene, the promoter is a DNA sequence, there are few transcription factors, and there is one RNA polymerase. In a eukaryotic gene, the promoter is a DNA sequence, there are many transcription factors, and there are several RNA polymerases.
9. Here is the structure of the gene:
E1 – I1 – E2 – I2 – E3 – I3 – E4
(E = exon; I = intron). Assuming that initiation of transcription begins at E1, the possible proteins are composed of exons 1234; 134; 124; and 14.
10. To keep a constant, low-level expression of repressor protein, the regulatory gene would have an inefficient promoter, and synthesis of the repressor would be constitutive.
11. You could sequence the relevant genes of colon cancer cells and look for mutations that lead to aberrant function, then isolate the proteins involved and determine that their functions are indeed abnormal. To show epigenetic silencing, you might sequence the promoters of the genes and look for epigenetic changes (e.g., cytosine methylation, which would be increased if there is transcriptional silencing). Then you could examine the tumor cells to see if the active proteins are there but in small amounts.

CHAPTER 17

1. c 2. b 3. e 4. e 5. b 6. b 7. c 8. c 9. a
10. One gene can produce several proteins by alternative splicing, which makes the proteome highly complex. In addition, many proteins are modified after translation, and this contributes to even more protein diversity. The metabolome is highly variable from cell to cell and from one time to another. It is determined not only genetically but also by responses to environmental conditions.
11. While all of these plants have the same basic genes for “life” as well as “plant” functions (e.g., photosynthesis, cell-wall formation, flowering), there are some genes (and proteins) that are specialized for each plant (e.g., rice genes for growing under water, genes for timing flowering, genes for seed-storage proteins).
12. (a) Extract genomic DNA from the patient's cells and analyze it for SNP polymorphisms. If the SNP that correlates with kidney cancer is present, he has an increased susceptibility.
- (b) Isolate both normal and cancerous kidney cells. Do a metabolomic profile on the kidney cancer cells and the normal kidney cells using chemical analyses for small molecules. By comparing the profiles, generate a metabolomic “signature” for the kidney cancer cells. Next, examine the metabolomic profile of kidney tissue from the patient and compare it with the metabolomic signature for kidney cancer cells.
- (c) For possible drugs involved in kidney cancer treatment, isolate many cancers (or examine stored tissues) and do a SNP analysis, correlating tumor response to the drug with the SNP polymorphism. Then isolate some of the patient's tumor cells and examine the DNA for SNPs that relate to drug response. Use the drug that the patient's genome indicates will be effective.

CHAPTER 18

1. b 2. c 3. e 4. a 5. e 6. d 7. b 8. c
9. Both PCR and cloning begin with a gene sequence. In PCR, the sequence is amplified in the test tube. In cloning, the sequence is amplified by an organism (typically bacteria). In PCR, amplification is achieved by synthesizing primers that bind to either end of a target DNA sequence and adding nucleotides and DNA polymerase. The doubled DNA is then denatured, and the process is repeated 20 to 40 times.

In cloning, the target DNA is inserted by restriction and ligation into a vector, which has an origin of replication that will function in the organism where amplification will occur. The vector is added to the host cells, which are cultured and divide many times, amplifying the target DNA along with the host chromosome. The vector is then removed from the host cells and cut with a restriction enzyme, releasing amplified, cloned target DNA.

PCR is much simpler and faster but has artifacts where inappropriate fragments of DNA are amplified or sequence errors are introduced by DNA polymerase. Cloning yields the correct DNA without mutations but involves host cell culture and time-consuming DNA purification steps. See Figure 18.12. A simple table can answer this question.

	Conventional	Recombinant DNA
(a) Sources of new genes	Other plants of same species	Any organism or synthetic DNA
(b) Number of genes transferred	Often many	One
(c) How long it takes	At least one growing season, usually many	Weeks

10. (a) The target gene would be inserted into an expression vector with a promoter such that the gene would be expressed in the developing seed. The vector could be added to cultured wheat cells, and those cells carrying the vector selected (the vector could carry a reporter gene for resistance to an antibiotic). The cells could be induced to form a wheat plantlet, which would be transferred to the field and the seeds examined for the new protein.
- (b) The target gene could be inserted into a sheep expression vector containing the lactoglobulin promoter so that the gene would be expressed in milk glands. The recombinant vector would be inserted into sheep egg cells. After the female offspring grew up, their milk could be tested for the presence of the human enzyme.
11. Public concerns include the artificiality of unnatural interference with nature, the safety of these foods for human consumption, and environmental dangers if non-host plants receive recombinant genes.

CHAPTER 19

1. c 2. b 3. a 4. e 5. a 6. b 7. c
8. (a) All neuronal precursors might undergo apoptosis and no neurons would form.
- (b) The *p21* gene would be activated and the cell cycle would be blocked; in the presence of other factors, muscle cells would form.
- (c) There might be no gradient of the protein in the developing limb and therefore no differential development of digits—all the digits would be fingers.
- (d) The hunchback protein gradient would not form properly and the embryo would not establish its anterior–posterior axis.
9. (a) No apoptosis would lead to too many cells in developing organs, and the organs would not form properly.
- (b) No gradient of hunchback protein would form, and there would be no posterior end determination in the developing fruit fly.
10. A mutation that caused expression of class A genes instead of class C genes. This would lead to an AB combination instead of AC, and petals would develop instead of stamens.
11. Mechanisms might include cell-cycle inhibition as a result of Cdk blocker; induction of transcription of certain genes; and cytoplasmic segregation, so that when a cell divides only one daughter cell gets a factor important in determination.
12. One could analyze mRNA in egg cells, in the parent differentiated cells, and in the reprogrammed cells. This could be done by reverse transcriptase PCR or by gene expression arrays.

CHAPTER 20

1. c 2. a 3. a 4. c 5. c
6. If the expression of Gremlin were blocked, this protein could not inhibit BMP4 signaling. The cells in the webbing of the feet would undergo apoptosis, and the duck would be born with unwebbed feet.
7. All of the hatchlings at any temperature would be expected to develop into males. Aromatase is required to convert testosterone into estrogen, which is required for female development.
8. The coexpression of *Hoxc6* and *Hoxc8* appears to be important in the development of thoracic vertebrae (the vertebrae with ribs). This is a short region in

mice, and mice have only a small number of thoracic vertebrae, and therefore a short body. In snakes, the coexpression of *Hoxc6* and *Hoxc8* along a much greater length of the embryo results in a much larger number of thoracic vertebrae, and therefore a much-elongated body.

9. The results support the conclusion that higher levels of BMP4 expression result in greater cartilage diameter on the beaks of developing chickens.
10. The observations are consistent with the hypothesis that there has been selection in some human populations for mutations on the enhancer that controls expression of the glycoprotein in red blood cells. This genetic change would be expected to have a selective advantage in human populations that are exposed to malaria at high levels, because the mutation confers greater resistance to malaria in humans that carry it.

CHAPTER 21

1. d 2. d 3. d 4. e 5. b
6. Humans select traits in domestic plant and animal populations based on our interest in the trait, rather than on how it affects the natural reproductive rate or survivorship of the organisms. Many of the traits artificially selected by humans would not be advantageous in wild populations. For example, humans have selected many cattle breeds for high body fat and high body weight. These traits result in large calves, which in turn result in calving difficulties for cows. Ranchers often have to assist in the birth of such calves, because the calf (and likely its mother) would often die without such assistance. In a natural population, there would be selection for smaller calf size and birth weight, which would increase the successful reproductive rate and survivorship.
7. Behaviors can respond to environmental cues that are predictive of future conditions, and these behaviors can be selected for if they are under genetic control. For example, day length becomes shorter as we move closer to winter, so individual mammals have a survival advantage if they respond to shortening days by going into hibernation. In this case, the environmental cue (day length) is predictive of future environmental conditions (the cold of winter).
8. Natural selection cannot act when there is no effect on the effective reproductive rate of the organism. Diseases such as Alzheimer's usually occur long after the reproductive years have passed. As long as the disease does not affect the relative likelihood of the survival of the affected person's offspring (as a result of reduced parental care, for example), we would not expect natural selection to lead to any reduction in Alzheimer's disease in human populations.
9. (a) Frequency of allele *a*: 0.60; of allele *A*: 0.40
- (b) Frequency of genotype *aa*: 0.40; of genotype *Aa*: 0.40; of genotype *AA*: 0.20
- (c) Expected frequency of genotype *aa*: 0.36; of genotype *Aa*: 0.48; of genotype *AA*: 0.16
- (d) We would expect some level of deviation because the assumptions of Hardy–Weinberg equilibrium are so restrictive. For example, the finite population size, the presence of mutation, any migration of individuals into or out of the population, gene flow from mating with adjacent populations, nonrandom mating within the population, or selection in the population could all lead to deviations from Hardy–Weinberg expectations.
10. The black mice and white mice are highly unlikely to be mating randomly with each other. The combined population is far from Hardy–Weinberg expectations, with far too few heterozygous (*Aa*) individuals. The much higher frequency of the *a* allele among the black mice, and of the *A* allele among the white mice, suggests that the black and white mice are mostly mating within color types, with few between-color-type matings. Another possibility, though, is that the population consists of two subpopulations (one of mostly black mice, the other of mostly white mice) that have only recently come together in the same location. These two hypotheses could be distinguished by following the mice through another generation. If mating is now occurring at random, we would expect the genotype frequencies to be similar to Hardy–Weinberg expectations after one generation of random mating.

CHAPTER 22

1. e 2. a 3. e 4. a 5. e 6. d
7. The classification is not currently monophyletic. Both genera could be monophyletic if Species 4 were moved from Genus B to Genus A; monophyly could also be achieved if all the species were included in the same genus.
8. Fossils can give us direct evidence of the character states of extinct lineages. For example, all modern birds lack teeth. Is the lack of teeth an ancestral or a derived condition? If we examine extinct species of theropods (the larger group of dinosaurs that includes the living birds), we see that they had teeth. Therefore we know that the lack of teeth is a derived condition in modern birds.
9. The estimated average rate of change is 0.9 amino acid change/500 million years, or 0.0018 amino acid change/million years. If we express this as a percentage rather than as a proportion, we would say there is (on average) 0.18 percent change in amino acid sequences per million years.

A-6 Answers to Chapter Review Questions

10. The West Nile virus in the United States appears to be most closely related to a strain of the virus isolated in Israel. A reasonable hypothesis is that the virus emerged in Africa in the 1930s and subsequently moved into Asia and Europe, probably multiple times. Then in the late 1990s, a strain of the virus from Israel appears to have been transported to New York, perhaps carried by mosquitoes on an airplane or in a cargo shipment. Once in the United States, the virus spread quickly in native bird populations across North America.

CHAPTER 23

1. e 2. c 3. a 4. e
5. If the only difference between the diverging lineages is at a single locus, then both of the new alleles must be functional when they interact with the products of other gene loci (in both lineages). Any interlocus genetic incompatibility produced by these new alleles would be expected to affect the parental lineages as well. In addition, there are many greater numbers of possible incompatibilities across different gene loci than there are within a single locus. Rather than two deleterious changes at the same locus (one in each lineage), the Dobzhansky-Muller model allows neutral changes at any pair of loci whose products interact. It is the negative interaction of these products in the hybrid between the two lineages that results in genetic compatibility.
6. If two different fusions of chromosomes occur in two different lineages, then the resulting chromosomes cannot pair normally in meiosis in the hybrids. If you attempt to diagram meiosis in the hybrid that would result from a cross of the divergent lineages in Figure 23.4, you will see that homologous pairings require parts of different chromosomes to align with one another. These chromosomes will then be pulled in two different directions as the cell divides in meiosis I, resulting either in a likely failure of the cell to divide, or an uneven distribution of the chromosome arms in the two daughter cells. Production of normal cells with an even distribution of the various chromosome arms will be limited, so the hybrids will produce few, if any, normal gametes.
7. A likely possibility is that the incompatible alleles have not yet become fixed in the various strains, so only some combinations of crosses result in genetic incompatibility.
8. Species that arise in allopatry initially occur in separate, but usually adjacent, ranges (see Figure 23.6). Therefore we would expect many closely related species to exhibit this same pattern. The ranges of highly mobile species are more likely to change over time, so the pattern should be strongest among relatively sedentary species.
9. There are many possible designs of experiments that might prove informative. Here is an example of one that would examine the effect of flower position on pollinator attraction: Take one species of flower and divide the flowers into two groups. Position each flower to be either upright or pendant, then record the number and type of pollinators that are attracted to flowers in each group. Test to see if the differences between the two groups are statistically significant.

10. (a)

- (b) Yes, because the curve for the number of species lags behind the curve for the number of islands, but the two curves exhibit very similar changes in slope through time. As new islands arise, new opportunities for speciation also arise. The number of species at any one time is always just below the number of distinct islands.
- (c) There are currently 18 islands in the archipelago and only 14 finch species. This suggests that there are still opportunities for additional speciation by geographic isolation. Based on our graph from Question a, we expect populations of species that occur on two or more islands to diverge into distinct species over time. To test this hypothesis, we could collect samples of each population and examine genetic divergence among the samples. Significant genetic divergence among the populations on different islands suggests that the distance between the islands is a significant barrier to gene flow, so the populations are expected to diverge into distinct species over time.

CHAPTER 24

1. a 2. a 3. a 4. e 5. b 6. e
7. Molecular clocks work best when they are applied within a group of organisms with similar generation times and populations sizes. Population size makes little difference if all or most changes are neutral, but rates of change among deleterious and beneficial changes are affected by population size. In addition, it is important to make comparisons among homologous genes and proteins, since rates of evolution across different genes are likely to vary widely. When molecular clocks are used to make comparisons across species with very different generation times, it is necessary to account for the different generation times.
8. New mutations are introduced into the experiment shown in Figure 24.14 through the errors made in the PCR amplification step. In other words, the mutation rate is a function of the error rate of the DNA polymerase. Using a different DNA polymerase with a higher error rate would increase the overall mutation rate of the experiment, and that would increase the variation in the population of molecules. Another possible answer is to add a mutagen to the PCR amplification step, which would also increase the mutation rate of the experiment. Any process that increases the mutation rate would be expected to increase the genetic variation present in the pool of molecules prior to the next round of selection.
9. This problem can be investigated by sequencing and comparing the genes for opsins in surface-dwelling (eyed) and cave-dwelling (eyeless) crayfishes. If the genes of the eyeless species are no longer under any selection, we would expect to observe a similar rate of synonymous and nonsynonymous substitutions in the genes. If there has been strong selection for a new function (something other than vision), we would expect a higher rate of nonsynonymous substitutions compared with synonymous substitutions (indicating positive selection). We would compare these rates to the rates seen in the surface-dwelling (eyed) species. In the surface-dwelling species, we would expect to see a higher rate of synonymous compared with nonsynonymous substitutions, which is expected under purifying selection.
10. (a) Codon numbers 12, 15, and 61 are likely to be evolving under positive selection for change because these three codons have each experienced a higher rate of nonsynonymous substitutions (which give rise to amino acid replacements) relative to the rate of synonymous substitutions.
- (b) Codon numbers 80, 137, 156, and 226 are likely evolving under purifying selection, as the vast majority of changes at these codons are synonymous substitutions, which do not result in amino acid replacements. Substitutions that result in amino acid changes (nonsynonymous substitutions) undoubtedly occur, but they are usually selected against in the population. Codon number 165 has experienced similar numbers of synonymous and nonsynonymous substitutions. However, since there are approximately three times as many possible nonsynonymous substitutions as there are synonymous substitutions, the number of synonymous substitutions is slightly higher than expected if the rates of each type of substitution are equal. Codon 165 may be evolving under weak purifying selection; it is the codon that is closest to neutral among the codons shown in the table.

CHAPTER 25

1. b 2. c 3. a 4. c 5. b 6. c
7. There are many possible answers, but four familiar examples include the study of Earth's past atmosphere by examining the chemical composition of rocks; the study of past climates by examining the growth rings of trees; the study of continental drift by examining the geological record; and the study of the origins of the universe (the "Big Bang") by examining the speed at which galaxies are moving apart.
8. Relative dating provides us an order for events; we learn that Event 1 happened before Event 2. But absolute dating provides us with an estimate of the timing of those events. It is important to know not just that Event 1 occurred before Event 2, but also how much time separated the two events.
9. Multicellular organisms require higher concentrations of oxygen, and the levels of oxygen increased throughout the Precambrian. By the end of the Precambrian, atmospheric oxygen levels were sufficiently high to support a variety of multicellular organisms. In addition, the end of widespread glaciation (the "snowball Earth" period) near the end of the Precambrian probably allowed multicellular organisms to flourish.
10. There are many possible experiments that could be devised. For example, the effects of changing oxygen concentrations on other species (besides flying insects, such as the *Drosophila* used in the described experiment) could be tested. An ideal study organism would have a short generation time (so that many generations could be followed in the course of the experiment) and would be easy to raise in the laboratory. For example, guppies could be raised in elevated and reduced oxygen concentrations, and evolution in the size of the swim bladder (a site of oxygen uptake) could be evaluated as a response.

CHAPTER 26

1. e 2. c 3. e 4. b 5. b 6. d

7. Ribosomal RNA genes are universally present across organisms. They evolve slowly, so they can be compared among the most distantly related species. They are present in multiple copies, so they were relatively easy to isolate and sequence in the earliest days of gene sequencing. Also, since they are required for protein synthesis, and already present in all cellular species, the possibility of lateral gene transfer is greatly reduced. In contrast, different types of metabolism have arisen repeatedly in the history of prokaryotes, so species with similar types of metabolism may not be closely related. Cell structure is useful for identifying some major groups of prokaryotes (Gram-positive versus Gram-negative groups, for example), but the differences are too few to be of great use in classifying most species.
8. A laterally transferred gene does not represent descent from a common ancestor and thus does not reflect a true evolutionary relationship.

Expected tree based on gene X:

Expected tree based on consensus of non-transferred genes:

9. Most, but not all, biologists consider viruses to be living organisms. Viruses have their own genomes, and they are composed of proteins much like cellular organisms. They evolved from other living species, and they are clearly a part of life. However, viruses are not composed of cells, and they depend on cellular hosts to carry out many of their biological processes. For these reasons, some biologists consider them to be nonliving components of their cellular hosts rather than distinct living organisms.
10. There are many possible answers, but one widely used approach for detecting new life forms (in any environment, including high-temperature environments) is to directly isolate and amplify conserved gene sequences. The ribosomal RNA genes are often used for such detection because they evolve very slowly and are required for protein synthesis. DNA could be extracted from high-temperature environments, and any ribosomal DNA genes that were present could be amplified and sequenced. The sequences would then be compared with the ribosomal RNA genes of other known species of prokaryotes to classify the organisms living in the extreme environment.

CHAPTER 27

1. e 2. c 3. e

4. (a) Foraminiferans have external shells of calcium carbonate, whereas radiolarians have long, stiff pseudopods and radial symmetry. The external shells of foraminiferans and the internal skeletons of radiolarians are both important components of ocean sediments and sedimentary rocks.
- (b) Ciliates are covered with numerous hairlike cilia, whereas dinoflagellates generally have two flagella (one in an equatorial groove, and the other in longitudinal groove). Both ciliates and dinoflagellates have sacs, called alveoli, just beneath their plasma membranes, which identify them as alveolates.
- (c) Diatoms are unicellular and are typically composed of two nested plates (like a petri dish). Brown algae are large, multicellular organisms composed of branched elements or leaflike growths. Both diatoms and brown algae are photosynthetic.
- (d) The vegetative unit of a plasmodial slime mold is a plasmodium: a wall-less mass of cytoplasm containing numerous diploid nuclei. The vegetative unit of cellular slime molds consists of separate, single amoeboid cells. In both groups, when environmental conditions become unfavorable, the vegetative units form fruiting structures.
5. The independence of sex and reproduction in ciliates suggests that sex has functions apart from reproduction. Sex is important for recombining genes,

which is important for several reasons. Sex allows populations of organisms to avoid the accumulation of deleterious alleles, and it allows the formation of new combinations of beneficial alleles. Thus even organisms that reproduce asexually generally have some other means of achieving sexual recombination of their genomes.

6.

Using the formula for a correlation coefficient shown in Appendix B, $r = -0.948$.

7. The results show that earlier bloom dates are associated with higher survival indices. The relationship between these two measures is very strong and nearly linear, resulting in a correlation coefficient of $r = -0.948$. As noted in the question, larval haddock depend on these blooms for both cover from predation and as a food source. A reasonable hypothesis for this is that earlier blooms provide better cover and more food for the larval haddock, so survivorship of the larval fish is higher in years when the phytoplankton blooms occur earlier. Another (not mutually exclusive) possibility is that the earlier blooms benefit other species that the haddock consume as food, or that the potential predators of haddock target the phytoplankton instead of the haddock.
8. The three rRNA genes of corn are not one another's closest relatives because the nuclear, mitochondrial, and chloroplast genomes have different origins, and the relationships shown in the tree reconstruct the endosymbiotic events that gave rise to mitochondria and chloroplasts.
9. The mitochondrial rRNA gene of corn is more closely related to the rRNA gene of *E. coli* than it is to the nuclear rRNA genes of other eukaryotes because the mitochondria were derived from an endosymbiosis with a proteobacterium. Likewise, the chloroplast rRNA gene of corn is more closely related to the rRNA gene of *Chlorobium* than it is to the nuclear rRNA gene of corn because the chloroplasts were derived from an endosymbiosis with a cyanobacterium.
10. The human and yeast mitochondrial rRNA genes would be expected to cluster on the tree closest to the corn mitochondrial rRNA gene because all of these genes are descended from the same endosymbiotic event (the origin of mitochondria). The human and yeast mitochondrial rRNA genes would be more closely related to each other than either is to the corn mitochondrial rRNA gene because fungi and animals are more closely related to each other than either is to plants (as can be seen in the relationships of the nuclear rRNA genes).

CHAPTER 28

1. c 2. e 3. b 4. b 5. d

6. Microphylls are usually small and typically have a single vascular strand. In contrast, megaphylls are larger and typically contain branched veins. Microphylls may have originated as sterile sporangia. Megaphylls may have originated from flattening of branching stems, between which photosynthetic tissues developed. Among modern plants, microphylls are found in lycophytes, whereas megaphylls are characteristic of the euphyllophytes (such as ferns and seed plants).
7. One advantage of heterospory is that it allows a greater degree of outcrossing, since there are separate male and female gametophytes.
8. Both mosses and ferns are homosporous, and both alternate between a diploid sporophyte and a haploid gametophyte generation. However, the gametophyte generation is the large, dominant portion of the moss life cycle, whereas the sporophyte generation is the large, dominant portion of the fern life cycle. The sporophyte of a moss is completely dependent on the gametophyte, whereas the sporophyte of a fern becomes independent of the gametophyte.
9. Yes. Heterospory is an example of a trait that appears to have evolved multiple times among different groups of vascular plants.
10. One possibility is to examine leaf size as a function of thermal environment among close relatives of living plant species. We might predict that large leaf size is restricted in hot, dry climates but favored in cooler, wetter climates.

CHAPTER 29

1. d 2. a 3. d 4. a 5. a
6. To be functional as a reproductive organ, a flower would need to have at least a carpel or a stamen. The petals function largely for pollinator attraction, and so can easily be lost in wind-pollinated species. The sepals function mostly to protect the flower in bud, and so may be lost in species with simplified flowers.
7. The fossil record is not a complete record of life on Earth. Early angiosperms may have been limited in distribution, or may have lived in environments that were not compatible with easy fossil formation. It is likely that the early angiosperms were not very abundant or widespread. They apparently underwent a rapid radiation in the Cretaceous, where they become common in the fossil record.
8. .

9. One approach to this problem is to calculate a linear trend line for survivorship of moth mullein (*Verbascum blattaria*) seeds by calculating a linear regression line (see Appendix B) and then projecting it forward in time to the point where it intersects zero percent survival. The resulting regression equation is $y = 102.09 - 0.62x$. The graph above shows this approach, which predicts that the last *Verbascum blattaria* seeds would germinate in about Year 165 of the experiment (set y to 0, and solve for x using the regression equation; the result is $x = 164.7$ years). This approach assumes a linear decline in viability of the seeds. It may be more reasonable to assume an exponential decay in seed viability (similar to radioactive decay; see Figure 25.1). If seeds decay exponentially, then we would expect some low level of survivorship of *Verbascum blattaria* seeds well beyond Year 165.
10. At least four factors are related to seed survivorship:
 1. Size of the seed: larger seeds have more food reserves (endosperm).
 2. Density of the seed coat: tougher seed coats provide better protection of the seed.
 3. Level of dormancy of the embryos: deeper dormancy results in longer survivorship.

CHAPTER 30

1. d 2. b 3. c 4. e 5. c
6. If it is a fungus, we would expect to detect chitin in the cells walls, whereas chitin would be absent if it is a plant. We could also examine the specimen for the presence of chloroplasts, which would be expected to produce the green coloration in a plant but not in a fungus. If it is a vascular plant, we would expect to observe vascular tissues in the sample, which would be absent if it is a fungus. We could also sequence a conserved gene from the sample, such as a ribosomal RNA gene, and compare the sequence phylogenetically with other fungi and plants.
7. It is because the nuclei remain separate in dikaryons, even though the two nuclei are contained within a single cell.
8. Fungi play a critical role in decomposition of plants and parts of animals. If there were no more fungi, there would be enormous accumulation of the remains of dead organisms, especially the cellulose and lignin of plants.
9. Site 5 shows the highest diversity and density of lichens and so is probably farthest from the city center. Site 4 is next, followed by Site 1, then Site 3, and finally Site 2. In addition to distance from the city center and prevailing wind direction, other predictive factors could include distance to point-pollution sources (such as factories or power plants) and distance to major highways (a source of pollution from automobile exhaust). Other answers are also possible; it is important for such studies to control for factors such as the species of tree examined and the exposure of the branches to similar light and humidity conditions.
10. One common source of fungal contaminants in plant samples is symbiotic fungi, including endophytic fungi and mycorrhizal fungi. In either case, it is usually possible to collect specific tissues from the plant that exclude these symbionts. If our hypothesis about the source of the fungal genes is correct, then the fungal sequences should be absent from these symbiont-free tissues.

CHAPTER 31

1. d 2. b 3. c 4. d 5. d
6. (a) In radial symmetry, body parts are symmetrical across multiple planes that run through a single axis at the body's center. Animals with radial symmetry have no front or rear ends, and they are often sessile or drift freely with currents. If they move under their own power, they can typically move slowly equally well in any direction. In contrast, bilaterally symmetrical animals have mirror-image right and left halves divided by a single plane that runs along an anterior–posterior midline. They have a front end that usually contains a concentration of sensory systems and nervous tissues in a distinct head. Bilateral animals usually move forward in the direction of the head, so the head encounters new environments first.
- (b) Among the bilaterian animals, there are two distinct forms of gastrulation, or the initial indentation of a hollow sphere of cells early in development to form the blastopore. In protostomes, the blastopore eventually develops into the mouth of the animal. In deuterostomes, the blastopore becomes the anus.
- (c) Diploblastic animals have embryos with two cell layers (an outer ectoderm and an inner endoderm). The embryos of triploblastic animals have an additional cell layer between the ectoderm and the endoderm, known as mesoderm.
- (d) Acoelomate animals lack a body cavity enclosed by mesoderm. Pseudocoelomate animals have a body cavity enclosed in mesoderm; this body cavity contains the gut and internal organs composed of endoderm, but these latter organs are not lined with mesoderm. Coelomate animals have a body cavity that is enclosed with mesoderm, and the internal organs are also lined with mesoderm.
7. The answer to this question will depend on the reader's opinion. However, most biologists would answer that the phylogenetic analyses that result from analysis of animal genomes provide the most definitive evidence of animal monophyly.
8. Bilateral organisms have an anterior and a posterior end. As the animal moves through the environment, the anterior end encounters potential food or predators first. It is therefore advantageous for the sensory organs and central nervous system to be concentrated at the anterior end.
9. A slow metabolic rate requires a low energy budget, and hence a low intake of food.
10. Placement of glass microscope slides (or other smooth substrates for placozoan attachment) in warm tropical waters often results in colonization by placozoans. The glass slides can be suspended in water in survey areas, then later retrieved and examined for the presence of placozoans.

CHAPTER 32

1. e 2. d 3. b 4. d 5. d 6. e
7. Segmentation allows an animal to move different parts of its body independently, which allows for much greater control of movement. However, segmentation tends to constrain the body shape of an organism. Loss of segmentation is often favored in some parasitic and burrowing organisms that live in confined spaces.
8. Several answers are possible, but some examples of key innovations that appear to be associated with major episodes of diversification in protostomes include the evolution of the cuticle in ecdysozoans, the evolution of shells in mollusks, the evolution of jointed limbs in arthropods, and the evolution of wings for flight in insects.
9. Insects have been highly successful in terrestrial environments, in part because flight gives insects greater access to plants. Many insect species are specialists on one or a few plant species, and plant diversity is far greater on land and in freshwater environments than in the oceans. Although some insects live in fresh water for part or all of their life cycles, these freshwater environments are closely associated with surrounding terrestrial environments. Crustaceans have been much more successful in the oceans than have insects, and crustaceans may simply outcompete insects in marine environments.
10. All entomologists agree that many more species of insects remain to be discovered, but many entomologists think that Erwin's estimates were high. Each estimate is highly dependent on how representative *Luehea seemannii* is as a tropical forest tree. If the average tropical forest tree has many fewer host-specific beetle species than does *Luehea seemannii*, then these estimates would be inflated. Likewise, overestimating the number of tropical forest trees, or the percentage of ground-dwelling beetles, or the percentage of all insects that are not beetles, would lead to further inflation of the estimates. In addition, species diversity of beetles may be higher in Panama than in other areas of the tropics. However, any of these estimates could be underestimates as well. Each of Erwin's assumptions is now being tested; these tests require extensive work on additional species of trees, additional groups of insects, and in additional areas of the world.

CHAPTER 33

1. d 2. a 3. d 4. a 5. e 6. b

7. The four appendages common to most vertebrates are the two pectoral appendages and the two pelvic appendages. In most swimming vertebrates, these appendages function as fins. They are commonly used for propulsion (especially the pectoral fins) but are also used for steering, stabilization, and manipulation of the body position in water. Among tetrapods, the appendages are often modified into limbs used for walking, running, jumping, burrowing, climbing, grasping, and manipulating objects. There have been several reversals to fin-like limbs used by aquatic tetrapods (several times among amphibians, turtles, birds, and mammals, for example). There have also been at least three origins of the pectoral limbs of tetrapods into wings for powered flight (among birds, bats, and the extinct pterosaurs). There have also been several other modifications of the limbs for gliding (in fishes, amphibians, reptiles, and mammals). One or both pairs of appendages have been lost (or greatly reduced) in many groups of fishes, amphibians, reptiles (including birds), and mammals. Some well-known examples of limb reduction or loss include the completely legless caecilians and snakes, the loss of external hind limbs in whales and manatees, and the greatly reduced forelimbs of flightless birds.
8. Amphibians exchange gases and fluids through their permeable skins. This makes them highly vulnerable to many environmental toxins. Many species of amphibians have a biphasic life cycle, so they are vulnerable to habitat degradation and loss of both aquatic and terrestrial environments. Most amphibians do not move long distances, so they do not easily move into new habitats when their local environment is destroyed. For these reasons, they are also sensitive to rapid climate changes. Many species of amphibians have highly specialized habitat requirements and live in very restrictive ranges. Habitat loss or changes within these restricted ranges often result in extinction.
9. Fossil remains of extinct theropod dinosaurs shows that many features once thought to be restricted to birds, such as feathers, actually evolved much earlier among the theropods. Other typical “bird” morphological features, such as air-filled bones and a furcula (wishbone), are also typical of the larger group of theropods. Among living reptiles, DNA sequence analyses clearly unite birds with the crocodilians (the other living archosaurs). The combined evidence from many sources that birds are a surviving group of theropod dinosaurs is now overwhelming.
10. Hair evolved in the ancestor of mammals; feathers evolved among theropod dinosaurs (seen today among the birds). Among the living tetrapods, birds and mammals are endothermic. Hair and feathers provide body insulation for mammals and birds, respectively. Without these forms of insulation, the maintenance of metabolic body heat would be difficult. Fossil evidence shows that many extinct theropod dinosaurs also had feathers, so many paleobiologists predict that they were endothermic as well. Endothermy would also be expected in large, active predators—a description that fits our current view of many theropod dinosaurs.

CHAPTER 34

1. b 2. e 3. a 4. b 5. b 6. d 7. c 8. c

9. The cell types can be compared using a table.

Structure/Function	Sclerenchyma	Collenchyma
Cell walls	Secondary, thickened	Primary, thicker at corners
Flexibility	Less flexible	More flexible
Cell conditions	Some dead (apoptosis)	Alive
Presence	Wood, bark	Petioles, growing areas

10. Primary growth involves cell division and cell enlargement, and typically results in growth of an organ in length. Secondary growth involves growth of an organ in thickness, by the addition of more cell layers. Only some angiosperms undergo secondary growth. Herbaceous plants such as peonies have only primary growth. Woody plants such as trees have both primary and secondary growth.
11. The initials are still 1.5 meters above the ground today because the plant grows in height at its apex.
12. Some examples might include a larger root apical meristem to produce thicker carrots and reduced internode growth to produce compact heads of cabbage.

CHAPTER 35

1. c 2. d 3. b 4. b 5. d 6. e

7. Epidermal cells have external walls with a waxy cuticle, which makes them repel water. The epidermal cells of roots might have a thinner (or absent) cuticle, as they take up water; and leaves and stems a thicker cuticle, to conserve

water. In addition, the epidermis of leaves, and to a lesser extent stems, has stomata, which regulate gas exchange (including loss of water vapor from the leaf interior).

8. A source is an organ such as a leaf that produces more sugars than it uses. A sink is an organ such as a root that produces less sugars than it needs and so imports sugars from a source. In a deciduous tree, a leaf might be a source in the summer, and roots a sink. But then in spring, the roots might be a source for the buds (newly emerging leaves).
9. To cross the fewest membranes and still get from the soil solution to the atmosphere by way of the stele a water molecule would follow this route: soil to root symplast to stele symplast to stele apoplast to xylem to leaf apoplast to leaf interior air space to stoma to atmosphere. A water molecule could follow this path by crossing as few as two membranes: 1) from soil into a root hair or root cortical cell across a root cell membrane; 2) out of a stele cell into the stele apoplast across a stele cell membrane. Getting from the soil solution to a mesophyll cell in a leaf would require crossing at least three plasma membranes: the two membranes listed for the previous route plus the mesophyll cell membrane (to get from the leaf apoplast into the mesophyll cell).
10. The mutation in the *HARDY* gene might cause increased expression of a gene that inhibits cation accumulation in stomata, thereby keeping them more closed and conserving water. To test this hypothesis, you could look at the response of stomata to light in the leaves of mutant versus wild-type plants. The stomata of wild-type plants should open rapidly in response to light (see Figure 35.9); the stomata of *HARDY* mutant plants might open more slowly or less wide.
11. (a) Yes. The difference in water potential between the soil and the leaf (1.7 MPa) is enough to overcome gravity and draw water to the top of the tree.
- (b) No. If the soil water potential decreased to -1.0 MPa, it would be more negative than inside the root cells and water would leave the roots (and enter the soil).
- (c) If all the stomata closed, the leaf water potential would not be as negative. This in turn would make the xylem water potential less negative, and so on down to the roots. This would make the difference between the leaf water potential and root water potential insufficient for water to flow from the roots to the leaves (toward a more negative water potential).

CHAPTER 36

1. d 2. d 3. c 4. a 5. c 6. d

7. The ability of chemists to detect low concentrations of elements is fairly recent. Before then, nutrient solutions thought to be pure often were not.
8. Heavy irrigation after a prolonged dry period may produce runoff of topsoil (the A horizon) and leaching of ions (especially anions) into the subsoil, making fewer nutrients available to plant roots. Converting land use from virgin deciduous forest to crops will change the composition of living organisms in the soil, as many organisms that live in association with tree roots will disappear. The soil structure and texture will also change, because roots will no longer be present to hold the soil together and make air spaces. The soil chemistry will change, because crops take up nutrients from the soils and the nutrients are removed from the system when the crops are harvested.
9. See Figure 36.10, the nitrogen cycle. There are numerous species that fix nitrogen. Loss of one species might allow others to expand and replace it. Loss of all the species would mean that only abiotic methods could be used for nitrogen fixation. This might reduce overall nitrogen in the soil, meaning less would be available for plant growth.
10. The experiment with mutant *Arabidopsis* suggests that *Arabidopsis* uses either its own or exogenous strigolactones for growth regulation and has the appropriate receptor and response mechanisms. This reinforces the idea that an ancient mechanism to attract beneficial microbes also is used for modern plant growth regulation. Or the reverse might be true: the original function of strigolactone might have been as a plant hormone and its role in plant-microbe interactions might have evolved later.
11. Because holoparasitic plants can gain reduced carbon through association with hosts, the genes encoding photosynthesis functions are not under selection pressure, because having them would not confer any survival and reproductive advantage for the parasites. So any mutation that renders such a photosynthesis gene nonfunctional will not be deleterious.

CHAPTER 37

1. a 2. d 3. b 4. b 5. a 6. b

7. Fire produces ash, which enriches the soil with plant nutrients. A seed that germinated as a result of fire could have an advantage in such a nutrient-rich soil.
8. If a single species has two mechanisms for breaking seed dormancy, then if environmental conditions for Mechanism A are not present, environmental conditions for Mechanism B might be. This enables the plant to respond to a wider array of environmental conditions. In addition, if the cue for, say, Mechanism A turns out to be misleading (not predictive of favorable conditions) and the

A-10 Answers to Chapter Review Questions

- seedling dies, there is still a second seed that can germinate at a different time (by Mechanism B), when conditions might be more favorable.
- The charcoal in the bag absorbs ethylene gas, which is released by ripening fruits. The lack of ethylene prevents over-ripening and decay.
 - To test for the relationship between corn stunt spiroplasma disease and gibberellins, you could measure gibberellins in plants infected with the bacterium and in normal plants; you might expect the spiroplasma-infected plants to exhibit a reduction in gibberellins. Another approach would be to infect normal plants with the spiroplasma and then spray gibberellins on them; you might expect this to reverse the stunt phenotype.
 - (a) See Figure 37.2 Add a mutagen to hundreds of corn seeds and plant them. In a screen, look for plants that are shorter, and propagate these.
(b) See Figure 37.11. If the transcription factor in the gibberellin signal transduction pathway is inactivated, the plants will be insensitive to gibberellin and be stunted. A mutation that inactivates the gibberellin receptor would have the same effect.
(c) Other potential effects might include reduced seed germination and reduced seedling growth due to lack of mobilization of stored reserves in the seed (see Figure 37.5). If the mutant is completely gibberellin-insensitive, these effects will *not* be overcome by adding gibberellin to the seeds as they germinate. If, however, the mutant is a dwarf because of reduced amounts of gibberellin in the plant (because of a mutation that affects gibberellin biosynthesis, for example), the germination effects could be reversed with exogenous gibberellin.

CHAPTER 38

- b 2. e 3. b 4. e 5. a 6. c
- In triploid cells undergoing meiosis, there cannot be pairing of homologous chromosomes in meiosis I. So meiosis I is abnormal and functional gametes do not form.
A fruit is formed from the ovary wall of the flower.
Seedless grapes are probably propagated by cuttings (vegetative reproduction).
- Poinsettias are short-day plants; they bloom at a time of year when days are getting shorter (in the Northern Hemisphere).
- No, it isn't necessary. Just a flash of light during a long night is enough to convert P_t to P_n and to change the photoperiod.
- (a) The mutation stabilized the CO protein.
(b) The mutation caused nonfunction of the FD protein.
(c) The mutation increased expression of the FLC protein.
(d) The mutation caused constitutive expression of the CO protein.
- Several approaches might be taken, such as a genetic screen for meiotic cells that do not separate chromosomes at anaphase I, or a search for proteins (and then their genes) that bind to SWI1 protein.

CHAPTER 39

- b 2. c 3. a 4. b 5. c 6. c
- A plant might make a secondary metabolite that kills an insect pest. Plants making this metabolite would be selected for in evolution. However, the insect might develop resistance to the metabolite. Then the insect population would increase while the plant population decreased—until another defense mechanism evolves. This is coevolution. For more examples, see Chapter 56.
- | | <i>Avr2Avr3</i> | Healthy | Healthy | Diseased |
|-----------------|-----------------|---------|---------|----------|
| <i>Avr1Avr4</i> | Healthy | Healthy | Healthy | |
- (a) The effects of reduced rainfall could include dehydration and osmotic stress. Genetic responses might include alterations in leaf anatomy, with a thicker cuticle to reduce evaporation; a more extensive root system to obtain water; and accumulation of solutes in the roots, which would reduce root water potential and result in more water uptake in dry soils.
(b) Flooding reduces the amount of O_2 available to the plants and results in reduced respiration. Adaptations might include increased production of pneumatophores or aerenchyma to supply air to submerged plant tissues.
(c) Wheat rust is a fungal pathogen. Plants can adapt by increasing the ability to seal off infected areas and reduce the spread of the fungus within the plant, by developing specific immunity, and by increasing production of phytoalexin and pathogenesis-related proteins that kill the fungus.
- You could feed one group of hornworms on normal plants and another group on genetically modified plants. The two groups could then be exposed to the parasite. If nicotine is protective, the hornworms that fed on normal plants should have fewer parasites.

CHAPTER 40

- c 2. c 3. a 4. d 5. b
- Feedforward information makes it possible to anticipate a physiological challenge to homeostasis and to take preemptive action by changing a set point or the sensitivity of a regulatory system. Feedforward information for the regulation of breathing could be the onset of exercise; for blood pressure it could be the fight-or-flight response to a threat; and for secretion of digestive juices it could be the sight, smell, or expectation of food.
- In the metabolic rate/environmental temperature curve in Figure 40.17, the equivalent of *HL* would be metabolic rate, as long as the animal's temperature is not rising or falling and the animal is not doing external work. *K* would represent the animal's thermal conductance, or how easily it loses heat; $1/K$ would be a measure of the animal's insulation. The curve projects to 0 at an ambient temperature equal to body temperature because this portion of the curve represents the extra metabolic effort necessary to compensate for heat loss to the environment. If body temperature and environmental temperature were the same, there would be no heat loss to the environment.
- Biological processes proceed more slowly at lower temperatures. Thus the lower the temperature of the heart or skeletal muscle, the slower will be its ability to generate a contractile force. This could pose a physiological challenge for highly active fish such as great white sharks or giant bluefin tuna that depend on fast swimming and endurance to catch prey. An evolutionary adaptation to this challenge can be seen in these fishes' vascular anatomy: blood from their hearts goes to the gills, where it exchanges respiratory gases but also comes into thermal equilibrium with the cold ocean water. Thus these fishes are sending cold blood to their body tissues.
- Basal metabolic rate ($ml\ O_2/hr$) vs. body mass (kg):

Heart size (g) vs. body mass (kg):

- The heart has to pump blood against the resistance of the vascular system. Since blood vessels go to all tissues of the body, the total length of blood vessels will be directly proportional to body size, and therefore total peripheral resistance will be directly proportional to body size. The other factor that determines how much blood the heart can pump is the heart rate. The total cardiac output is a function of the size of the heart and the number of times it beats per unit of time.
- Several factors that determine the heat transfer rate between the iguana and its environment are different in these two conditions. When basking on the lava rocks, the radiation absorbed will be higher and the heat conducted across the skin will be different in comparison to being in the water. Also, when the animal breathes it will be losing heat through evaporation of water in its airways.
An experiment in which the animal heats up and cools down in the same environment would offer stronger support for the conclusion that blood flow

to the skin is a critical factor. The iguana could be placed in water and in air at two different temperatures (e.g., 20°C and 40°C) to compare the rates of heating and cooling.

CHAPTER 41

1. b 2. a 3. d 4. e 5. e
6. The time course of a hormone signaling system depends on several factors, including the rate of release of the hormone, its half-life in the blood, and the interactions it has with its receptors. A hormone signaling system that controls a short-term process such as digestion would be expected to have a rapid (e.g., vesicular) release, a short half-life, and rapid action; these are attributes of a peptide hormone. A hormone signaling system that controls a long-term process such as embryonic development would be expected to have continuous release, a long half-life, and to be slow acting, attributes of a steroid hormone.
7. The high levels of synthetic male steroid hormones exert actions through the testosterone receptors that exist in both males and females. The usual effects of promoting muscle hypertrophy and male secondary sexual characteristics (e.g., hair, a deeper voice) will occur. In addition, the high level of negative feedback on the pituitary gonadotropes and on the production of GnRH by the hypothalamus will reduce testicular and ovarian functions in the males and females. Decrease of circulating estrogens in the females will cause reduction of breast tissue.
8. The most common cause of hypothyroidism is lack of iodine in the diet. Thyroglobulin continues to be produced, but there is a lack of functional T_3 or T_4 . As a result, the levels of TRH and TSH rise because of the lack of negative feedback. The elevated TSH induces continued production of thyroglobulin, resulting in goiter. The most common cause of hyperthyroidism is an autoimmune disease called Graves disease. An antibody to the TSH receptor is produced, and the binding of that antibody to the receptor causes activation of the signaling pathway that increases the production of thyroglobulin and the development of goiter. If there is adequate iodine in the diet, however, this condition results in increased secretion of T_3 and T_4 , which produces the symptoms of hyperthyroidism.
9. The large size of the larvae together with the lack of adult moths indicates that cycles of growth and molt of the larvae continued without the induction of pupation. The low temperature probably prevented the usual decline in the production and secretion of juvenile hormone by the corpora allata.
10. Insulin controls the entry of glucose into most cells of the body, but not neurons. When insulin levels fall, as happens during the postabsorptive state (i.e., after ingested nutrients have been fully digested), glucose entry into cells slows down and the cells convert to using other sources of energy. Neurons, however, always require glucose; their lack of insulin means that their access to an adequate glucose supply is protected during the postabsorptive state because there is no decrease in their ability to take up glucose from the blood. Also, the decrease in glucose use by other cells of the body preserves the glucose in the blood for use by the nervous tissue.

CHAPTER 42

1. a 2. e 3. e 4. c 5. d 6. a
7. See Figure 42.10. The antigen-binding site of an antibody has heavy and light chains in a unique three-dimensional configuration that binds a particular antigenic determinant. This is similar to an enzyme active site that binds a substrate. In both cases, binding is noncovalent. A major difference is in the result of binding: an antigen does not change its covalent structure when it binds to an antibody, whereas a substrate does change covalently when it binds to an active site.
8. Both immunoglobulins and T cell receptors have constant and variable protein regions, bind antigens, and have great variability in primary structure. T cell receptors are only membrane proteins of T cells. Immunoglobulins can be either membrane proteins of B cells or secreted proteins in the blood.
9. The father's haplotypes are A1B7D11 and A3B5D9; the mother's are A4B6D12 and A2B7D11. These two parents could not have the child with the genotype indicated.
10. There are thousands of different enzymes in an individual but potentially millions of different specific antibodies. Every cell in an animal has the genetic information for all enzymes. Each immunoglobulin, however, is derived from a unique gene (produced by DNA rearrangements) in a B cell or a clone.
11. Experiments might involve testing vaccinated people for neutralizing antibodies against HIV (humoral immunity) and looking for T cell activity against HIV-infected cells (cellular immunity).

CHAPTER 43

1. a 2. d 3. d 4. d 5. d 6. a
7. Leydig and thecal cells have similar functions and characteristics. They are both removed from direct contact with the developing gametes, and they both

produce testosterone. Sertoli cells and granulosa cells are both in direct contact with the developing gametes, and they support their development by providing nutrients.

8. Progesterone actions are required to maintain the endometrium in a condition that can support implantation and not degenerate, as occurs during menstruation. By blocking progesterone receptors, RU-486 prevents implantation and the maintenance of the endometrium.
9. Conditions that could favor the evolution of this sexual dimorphism are a sessile existence, dispersed populations, and availability of suitable habitats. If a larva lands on a suitable substrate, it will have high reproductive success if it is a female and can produce lots of eggs; eggs typically have resources that enable them to travel considerable distances if released into the water, and their probability of being fertilized is therefore high. A larva would have a lower probability of success if it developed into a solitary male and produced sperm; sperm have less ability to survive travel over long distances in the water to encounter eggs. However, if a larva lands on a female, it is guaranteed high reproductive success if it can fertilize all of the eggs that female produces. Therefore, by attaching itself to the female and minimizing all of its own physiological processes other than sperm production, a larva can achieve high reproductive success at very little cost.
10. It is likely that the man's offspring would all be daughters. The Y chromosome lacks some essential genes that are on the X chromosome; in the absence of the cytoplasmic bridges, the developing sperm that contain a Y chromosome would lack those gene products. Thus all viable sperm the man produces would contain an X chromosome. This would result in female offspring, since the mother would also contribute an X chromosome.

CHAPTER 44

1. e 2. a 3. d 4. b 5. b
6. You could inject Disheveled protein into the side of the fertilized egg opposite the gray crescent and see if a secondary organizer formed in that region of the resulting blastula. You could also inject the inhibitor of the Disheveled protein into the region of the gray crescent and see if that prevented the formation of the organizer.
7. You would be destroying the cells that normally migrate from the dorsal blastopore lip to form the notochord, and that also produce the signals that determine the anterior-posterior differentiation of the embryo. Thus you might see defects in the development of the nervous system or abnormal segmental development of the body.
8. The flow of fluid over Henson's node may be asymmetrical and thereby create different physical forces on the primary cilia of cells on either side of the node. These differential forces could influence the expression of *Sonic hedgehog*. Experiments to test this hypothesis could include using gene knockouts that eliminate the motile cilia around Henson's node, or experiments in which early embryos are cultured under conditions in which the flow across Henson's node is opposite that of the normal pattern. The prediction for the first experiments would be that the right-left asymmetry of organs in the embryos would be randomized. The prediction for the second experiment would be that the normal asymmetry of organ development would be reversed.
9. A possible mechanism would be cytoplasmic factors that are not distributed randomly or evenly throughout the cytoplasm of the oögonia or the spermatogonia. Thus when they divide by mitosis, factors that control the fates of the daughter cells could be received by one daughter cell but not the other.
10. At an early stage of blastulation (e.g., the 16- or 32-cell stage,) a few blastomeres could be removed from the embryo and cultured separately to produce a population of stem cells. The embryo could go on to develop normally, and the stem cells could be frozen for later use.

CHAPTER 45

1. d 2. b 3. c 4. e 5. c
6. When the stimulus occurs at some point along an axon and an action potential is stimulated, depolarizing current will flow in both directions, bringing adjacent areas of the axon to threshold. However, once an action potential is fired, the Na^+ channel inactivation gates close and make that section of the axon refractory to further stimulation until they open again. Thus the action potential cannot reverse its direction of propagation, and if the action potential begins at the axon hillock, it cannot reverse its direction of propagation and is unidirectional.
7. Excitatory synapses cause a depolarization of the neuronal membrane, and inhibitory synapses hyperpolarize it. These two influences are summed by virtue of the resulting membrane potential. If it depolarizes enough to reach threshold, an action potential will be fired at the axon hillock.
8. Because the GABA receptor is inhibitory, benzodiazepines would be expected to slow cognitive processes and make a person more likely to fall asleep.

A-12 Answers to Chapter Review Questions

9. The type of information that an action potential transmits depends on the nature of the sensory cell that generated the action potential and on the nature of the cell that receives input as a result of that action potential. Thus photoreceptors transduce light into action potentials, and those action potentials are interpreted as light in the visual circuits that receive those action potentials. Intensity of the stimulus is coded as the frequency of action potentials. Integration is achieved by the summation of excitatory and inhibitory influences on the target cells.

CHAPTER 46

1. d 2. a 3. e 4. e 5. c
6. Olfactory and taste receptors are both chemosensors that respond to specific molecules in their environment. Olfactory receptors, however, are neurons, whereas taste receptors are epithelial cells that communicate with neurons that are associated with them. Olfactory receptors express a family of genes for olfactory receptor proteins that are then localized on cilia that project out of the olfactory epithelium. All of these olfactory receptor proteins are G protein-linked and are metabotropic. Taste receptors are also located on cilia of the epithelial taste sensor cells. Bitter, sweet, and umami receptors are G protein-linked metabotropic receptors, but salt and sour receptors are ionotropic. The discrimination between an apple and an orange depends on integration of information from both the olfactory and the taste receptors.
7. The sensation of directional motion arises from the vestibular system, which includes the semicircular canals and the vestibule, which contains membranous structures containing a fluid—endolymph. At the base of each semicircular canal is a gelatinous projection, a cupula, that encases a cluster of stereocilia. Movement of the head causes movement of the endolymph, which then exerts force on the cupula and bends the stereocilia, generating action potentials in the vestibular nerves. The vestibule includes two membranous structures called the saccule and the utricle. In these structures, stereocilia tips are in contact with otoliths, which are membranous structures containing crystals of calcium carbonate. When the head is accelerated forward or backward, the momentum of the otoliths causes the stereocilia to bend in a direction that indicates the direction of movement.
8. Underwater, the external ear canals are filled with water. Unlike air, water is not compressible and therefore sound waves are transmitted through water as vibrational movements of the water. These movements exert greater forces on the tympanic membrane than air pressure waves do.
9. As happens in humans in the vestibular system, movements of the fish cause movements of the water in the lateral line canals. The resulting forces are transduced into action potentials by the hair cells and provide information about the movement of the fish through the water. Additionally, vibrations in the water generated by other organisms or physical events will cause movement of the water in the lateral line canal and be transduced into action potentials, providing information to the fish about its environment.
10. The owl depends on auditory stimuli to locate the mouse in total darkness. Directional information comes from the bilateral placement of the ears, which are equally stimulated when the owl is directly facing the source of the sound. The face of the owl is disc-shaped, which helps collect sound waves and direct them to the ears.

CHAPTER 47

1. d 2. d 3. c 4. c 5. a
6. The stab wound must have severed the sympathetic nerves on the left side of the man's neck. Activity in these nerves causes dilation of the pupil. Severing the sympathetic nerves on the left side would remove all sympathetic activity reaching the pupil on the left side, and therefore it would be more constricted. Similarly, sympathetic activity decreases activity in the salivary glands, whereas parasympathetic activity increases salivation. Thus withdrawal of sympathetic input would release the salivary glands from any inhibition that would counteract even low levels of parasympathetic input.
7. Eyes positioned on the sides of the head enable a wider field of vision. Eyes pointing in the same direction create a narrow field of vision but make depth perception possible. You would expect prey species to benefit from wider fields of vision. You would expect predator species to benefit from depth perception, which would facilitate pursuit and capture of prey.
8. Sleepwalking is more likely to occur in non-REM sleep for two reasons: there is motor inhibition in REM sleep, which renders the individual paralyzed; and the nature of sleepwalking activities does not match with the vivid, bizarre content of REM-sleep dreams.
9. We can break this question down into the different observations. First, the loss of motor control of the right leg indicates that motor commands are ipsilateral—they descend on the same side as the limb that is being controlled. The ability to sense painful stimuli applied to the right leg but not to the left foot indicates that the pain pathways cross over to the opposite, or contralateral, side of the spinal cord before they ascend to the brain. The reflex

movement of the right leg to a stimulus applied to the left foot indicates that reflex information is processed at the local level and does not require processing at higher levels of the central nervous system. The conclusion is that motor commands in the spinal cord are ipsilateral to the muscles being controlled but that the pain information ascending to the brain is contralateral. Finally, the different responses to pain and to touch indicate that these two modalities of somatosensory information travel in different tracks: touch ipsilaterally and pain contralaterally.

10. The fact that more slow-wave activity was seen over the right frontal cortex than over the left in response to exercising and training the left hand shows that the right side of the brain controls the left side of the body, and visa versa. This increase in slow-wave activity during sleep following the exercise/training suggests that this sleep slow-wave activity reflects either a restorative process or a learning process.

CHAPTER 48

1. b 2. c 3. b 4. d 5. c
6. One feature is the length of the muscle; half the length of a long muscle is more than half the length of a short muscle. Another feature is the location of insertion of the muscle on the bone; this determines the relative lengths of the effort arm and the load arm of the lever system created by the muscle, bone, and joint. If the ratio of load to effort arm is small, a large movement that can generate only relatively small forces is possible. If the ratio of load to effort arm is large, only small movements that can exert large force are possible.
7. If the break and healing have damaged the epiphyseal plate, and the primary and secondary areas of ossification fuse, the bone can no longer grow at that end.
8. The shoulders will fatigue first because they are not normally responsible for maintaining posture; they are adapted for rapid movements and sudden applications of large force. Thus shoulder muscles have a higher proportion of fast-twitch fibers. The leg muscles are postural muscles and have a higher proportion of slow-twitch fibers.
9. The action potential is conducted throughout the muscle cell by the system of T tubules. In the T tubules, the action potential causes conformational change of the DHP-ryanodine receptor complex. That change opens Ca^{2+} channels in the sarcoplasmic reticulum, and Ca^{2+} diffuses into and throughout the sarcoplasm. Ca^{2+} binds with the troponin units, causing the tropomyosin to expose the actin-myosin binding sites, cross-bridges to form, and the muscle to contract. When the Ca^{2+} concentration in the sarcoplasm falls as a result of being pumped back into the sarcoplasmic reticulum, the process reverses and actin-myosin binding sites are no longer available. The difference in time course of the contraction versus the action potential is due to the time that it takes for the Ca^{2+} to be released, diffuse throughout the sarcoplasm, and then be sequestered back into the sarcoplasmic reticulum.
10. The increased amount and duration of Ca^{2+} in the sarcoplasm causes increased contraction of the muscles and therefore an increase in muscle tension. The increase in muscle tension requires additional expenditure of ATP, raising metabolism and producing more heat. The increased metabolism causes elevated heart rate. This is in addition to the effect of the increased Ca^{2+} in the cardiac muscle itself.

CHAPTER 49

1. d 2. e 3. b 4. c 5. a
6. This fish would not be very active. It would move slowly. It would have a larger heart and larger blood vessels than fishes with hemoglobin, to accommodate a high flow of blood at low pressure. Its gill membranes would be well developed. It would have a high blood volume. Its jaws would show adaptations for sit-and-wait capture rather than pursuit. This fish occurs only in Antarctic waters because Antarctic waters are very cold and therefore the solubility of O_2 in those waters is high.
7. The total surface area for gas exchange is much smaller in a large air cavity than it is in many smaller cavities (alveoli) that add up to the same total volume. If the lung tissue is less elastic, the vital capacity of the lungs will go down, meaning less air can be exchanged during the breathing cycle. The less elastic lung tissue is also less permeable to respiratory gases.
8. Close to the end of inhalation, the pleural cavity pressure is reaching its maximum negative value. At the same time, the alveolar pressure is rising back up to being the same as the atmospheric pressure. Alveolar pressure would be most positive relative to atmospheric pressure at the midpoint of the exhalation phase.
9. Blood cells require energy. When in storage, their initial energy source is the glucose in the blood plasma, but as that supply gets depleted, blood cells also metabolize the intermediates in the glycolytic pathway. That includes 2,3-BPG. As the 2,3-BPG gets metabolized, there is less of it to bind to deoxygenated hemoglobin and therefore the affinity of the hemoglobin for O_2 increases. When

the affinity of the hemoglobin for O_2 gets too high, it can lower the P_{O_2} in the plasma to levels that are below the P_{O_2} in the plasma of a patient.

10. When you go up in altitude, the P_{O_2} in the air you breathe goes down, but the P_{CO_2} was already low at low altitude and remains low at high altitude. Thus at higher altitude there is less of a concentration gradient driving diffusion of O_2 into the blood, but no decrease in the concentration gradient driving CO_2 out of the blood. Thus the main stimulus for breathing goes down as the need to increase breathing goes up. As a result, the blood becomes hypoxic and triggers breathing by activating the carotid and aortic chemosensors. The increase in breathing blows off even more CO_2 , and breathing slows, which causes another bout of hypoxia and even a rise in blood CO_2 . That triggers another bout of rapid breathing, and this cycle repeats.
11. (a) The llama hemoglobin has a higher affinity for O_2 .
 (b) Llama hemoglobin would be advantageous at high altitudes because it can become 100 percent saturated at the low P_{O_2} of the high-altitude environment. Therefore the hemoglobin can carry a full load of O_2 to the tissues.
 (c) Llama hemoglobin allows the transfer of O_2 to occur at lower tissue P_{O_2} s.

CHAPTER 50

1. a 2. c 3. d 4. c 5. e
6. One factor is that at the beginning of a race there is a feedforward signal from the sympathetic nervous system that increases heart rate. Another factor is that the increased heart rate, together with the increased venous return to the heart from the exercising muscles, stretches the ventricles, which then contract with more force as described by the Frank-Starling law. This is due to the fact that a slight stretching of the sarcomeres optimizes the overlap of the actin and myosin fibrils for a maximum contraction. Increased breathing also increases the venous return and induces the Frank-Starling law.
7. There is no time when all four heart valves are open at the same time; if there were, the heart could not pump efficiently. Throughout diastole, the aortic and pulmonary valves are closed and the atrioventricular valves are open. At the beginning of systole, the atrioventricular valves close. There is a brief moment when all four valves are closed, until the aortic and pulmonary valves open, and stay open until the end of systole.
8. There are rapid responses and longer-term responses. A fall in blood pressure lowers the firing rate of baroreceptors in the great arteries. The decrease in baroreceptor input to areas of the brainstem that regulate cardiac function results in increased sympathetic and decreased parasympathetic output to the heart. This increases the heart rate and the force of contraction of the cardiac muscle (the fight-or-flight response). A slower response to blood loss is mediated by the kidney, which responds to the decreased blood pressure by increasing the release of renin, which in turn increases the activation of angiotensin circulating in the blood. Active angiotensin increases blood pressure by constricting peripheral blood vessels and stimulating thirst. Another slow response, stimulated by the fall in baroreceptor activity, is the release of ADH from the posterior pituitary. ADH increases the reabsorption of water by the kidney.
9. The cardiac muscle must be capable of generating and conducting action potentials. This may involve different variants of the ion channels involved in action potential generation and conduction. The cardiac muscle must be able to convert the action potential into the opening of Ca^{2+} channels in the sarcoplasmic reticulum, so there could be adaptive changes in the DHP and ryanodine receptors. Once Ca^{2+} is released into the sarcoplasm, it has to be resequenced into the sarcoplasmic reticulum, and that Ca^{2+} pump is likely to be adapted to operate at lower temperatures in the hibernator.
10. Your graph should look like this:

A similar graph for the right ventricle would have the same volumes but lower pressures.

CHAPTER 51

1. e 2. a 3. b 4. d 5. b
6. The rationale for a high-fat and high-protein diet is that it minimizes the secretion of insulin. Insulin promotes the uptake, metabolism, and storage of glucose by various cells of the body; it also inhibits the action of lipase in the adipose tissue. Thus with low insulin, tissues are more likely to metabolize fats and less likely to store them.
7. The following points might be included in your answer.
 - Insulin stimulates most cells of the body to take up glucose from the blood by stimulating the insertion of glucose transporters into the plasma membranes of those cells in the absorptive state.
 - Insulin inhibits lipase in the adipose tissue, so breakdown of stored lipids is decreased in the absorptive state.
 - Insulin stimulates the synthesis of triglycerides in the adipose tissue.
 - Insulin activates the enzyme that phosphorylates glucose as it enters cells, thereby preventing it from diffusing back out of the cells. This maximizes the uptake of glucose by cells.
 - Insulin activates the liver enzymes that synthesize glycogen.
 - The lack of insulin in the postabsorptive state decreases the uptake of glucose by most cells of the body and activates the enzymes of lipolysis and glycogenolysis.
8. Triglyceride in food is emulsified by bile in the duodenum to form micelles, which are broken down by pancreatic lipase into free fatty acids and monoglycerides. Both are absorbed across the plasma membranes of intestinal epithelial cells. In the intestinal epithelial cells, the free fatty acids and monoglycerides are resynthesized into triglycerides and packaged into chylomicrons, which also contain cholesterol and are coated with lipoproteins. The chylomicrons are secreted from the basal ends of the epithelial cells into the center of the intestinal villi, where they enter the lymphatic vessels and circulate through the lymphatic vessels to the thoracic duct, where they enter the blood.
 A *direct route* the fatty acid could take would be for the chylomicrons circulating in the blood to come into contact with the damaged endothelium of the coronary arteries and be absorbed into the plaque.
 In an *indirect route*, the chylomicrons could be taken up by liver or adipose tissue cells and the triglyceride stored. In the liver, the triglyceride can be repackaged to form low-density lipoproteins or very low-density lipoprotein particles, depending on the amount of cholesterol in the particle. These lipoproteins leave the liver and circulate in the blood. When they come into contact with the damaged endothelial cells of the coronary arteries, they bind to lipoprotein receptors, and their triglyceride and cholesterol are absorbed into the plaque.
9. Carbonic anhydrase catalyzes the hydration of CO_2 to produce carbonic acid that dissociates into H^+ ions and HCO_3^- ions. In the parietal cells of the stomach, H^+ is secreted into gastric pits and then flows into the stomach lumen. The bicarbonate ions are transported out of the basal side of the cells, where they are absorbed into the blood, raising blood pH. In the ducts of the pancreas, bicarbonate is transported into the lumen of the ducts; H^+ ions are transported out of the basal sides of the cells, where they are absorbed into the blood, lowering its pH.
10. The hypothalamic regulatory pathways control hunger and satiety, not energy use. This tells us that the side of the energy balance equation that is most important in contributing to obesity is Calories in. Of course, obesity can also result in decreased physical activity, which means that decreased Calories out can be a secondary factor in the causation of obesity.

CHAPTER 52

1. d 2. a 3. a 4. b 5. a
6. The glucose contributes to the osmotic concentration of the glomerular filtrate and therefore of the tubular fluid. This results in a greater volume of urine flowing through the collecting ducts and being excreted.
7. ACE inhibitors decrease the production of angiotensin II, the active form, from angiotensin I. Decreasing the level of angiotensin in the blood increases the glomerular filtration rate and therefore the production of urine. Losing more water in the urine lowers the blood volume and therefore the blood pressure. Blocking angiotensin also results in dilation of peripheral blood vessels, which lowers blood pressure, and decreases thirst, which helps maintain a lower vascular volume. Angiotensin stimulates the release of aldosterone, which promotes Na^+ reabsorption and therefore water retention.
8. The rate at which the inulin is filtered is equal to the concentration of inulin in the blood ($[I_b]$) times the glomerular filtration rate (GFR). The rate at which inulin is excreted is equal to the concentration of inulin in the urine ($[I_u]$) times

A-14 Answers to Chapter Review Questions

the urine flow rate ($V = 1 \text{ ml/min}$). Since all inulin that is filtered leaves the body in the urine, the rate at which it is filtered must equal the rate at which it is excreted. Therefore $[I_u] \times \text{GFR} = [I_u] \times V$, and $\text{GFR} = [I_u] \times V / [I_u]$.

9. Any difference in the rate at which the substance (S) is filtered versus the rate at which it is excreted will be due to tubular reabsorption of tubular secretion. If more of S is excreted than filtered, then S must be secreted by the renal tubules. If less of S is excreted than filtered, then S must be reabsorbed by the tubules. Therefore $[S_u] \times \text{GFR} - [S_u] \times V =$ the rate of reabsorption (if negative) or secretion (if positive) of S.
10. At high altitude, the concentration difference driving O_2 across the alveolar membranes and into the blood decreases, but the concentration difference driving CO_2 across the alveolar membranes and into the expired air does not change. The increased breathing rate driven by hypoxia will therefore blow off too much CO_2 and the pH of the blood will increase, which will suppress breathing. Bicarbonate is filtered into the glomerular fluid; as that fluid passes through the renal tubules, H^+ ions are excreted, resulting in the formation of H_2CO_3 , which dissociates into CO_2 and H_2O . The CO_2 is reabsorbed into the tubule cells, where carbonic anhydrase catalyzes its hydration to H^+ ions that are secreted back into the tubular fluid and bicarbonate ions that are secreted back into the extracellular fluid. Blocking carbonic anhydrase results in fewer H^+ ions being secreted into the tubular fluid and more bicarbonate ions remaining in the tubular fluid to be excreted. The retention of H^+ and excretion of bicarbonate lower the blood pH, and that stimulates increased breathing. However, the increased bicarbonate in the tubular fluid raises the osmotic concentration of that fluid, causing more water to be excreted.

CHAPTER 53

1. b 2. e 3. c 4. a 5. d 6. e 7. a 8. e
9. The development of brain circuitry controlling the sexual dimorphism in urination behavior is influenced by the levels of estrogen or testosterone that are circulating in the blood during the early postnatal period. Estrogen must prevent the development of the neuronal patterns of connectivity that are responsible for the male behavior.
10. The major difference between the eusocial insects and vertebrates is the haplodiploid mechanism of sex determination in the insects. This means that a female worker that is a daughter of the queen shares more genes with sisters—the queen's offspring—than she would with her own offspring, which would have a different father. Thus raising a sister contributes more to the female worker's inclusive fitness than raising a daughter would. Haplodiploidy is not found among vertebrates, so this powerful selective force does not operate among them.
11. The variability in the undirected song allows the male to adapt his song to the local variant. The directed song is probably more effective in attracting a female because it more accurately identifies the male as a member of the local population, and is also more effective in competition with neighboring males.
12. Since male cowbirds will not hear the song of his father, his song pattern should be genetically determined. Females probably learn the song of host species and thereby learn to identify and locate potential host nests. You could test the hypothesis about males by raising them in isolation to see what songs develop as they mature. You could test the hypothesis about the females by giving them a choice test such as that done with the zebra finches in testing directed and undirected song preferences (see Figure 53.8). Give each female cowbird a three-chambered cage, and play the songs of host species and non-host species in the opposite end chambers. Place the test bird in the middle chamber. Record the amount of time the female spends in each end chamber as a measure of preference. Another experiment would be to bring a host nest with cowbird eggs into the laboratory and raise the cowbirds in the presence of recordings of another species song. Then repeat the choice experiment with the host's and the other species' songs being played.
13. The classical data suggest that the hygienic behavior is controlled by two genes to give the typical Mendelian ratio of 3 to 1 with 50% hybrid, 25% homozygous dominant, and 25% homozygous recessive. The QTL analysis, however, indicates that more than two genes are involved. The difference in these results could be due to there being two major-effect genes and several modifying genes.

CHAPTER 54

1. d 2. d 3. a 4. c 5. c
6. Based on its location and its weather conditions, the matorral should have vegetation typical of that found in other areas with Mediterranean climates. Vegetation should be (and is) tough, shrubby and fire-adapted, with slender, leathery leaves and seeds either stored in fire-safe cones or equipped with elaiosomes and dispersed by ants.
7. The fact that species in the genus are known in Australia and in southern Africa, it is likely that the genus originated before the breakup of Gondwanaland, the supercontinent comprising Antarctica, South America, Africa and Australia.

Other species in the genus thus might be found in South America (contemporary conditions are too cold to maintain spider life in Antarctica today but the possibility exists that fossil species in the genus might be found).

8. Examining the x axis of the figure suggests that, if average low temperatures shift upward by five degrees C, the tundra biome would experience a substantial decrease in geographic extent (and may cease to exist altogether); boreal forest might also experience a reduction in geographic extent.
9. The extensive radiation of *Drosophila* species in Hawaii suggests that the genus originated here. Hawaii is an isolated island system and its distance from any continents means that dispersal to such remote islands of ancestral species would likely be very rare. Other lines of evidence to suggest that the genus originated in Hawaii would be whether fossil ancestral taxa are found only in Hawaii or anywhere else in the world. If ancestral taxa are not known from any other continent, it's very likely that the genus originated and subsequently diversified in Hawaii (and then dispersed elsewhere).

CHAPTER 55

1. d 2. c 3. b 4. d 5. a 6. d
7. In both of these cases, human management strategies will be working against the organisms' intrinsic rates of increase. Populations of long-lived organisms with low reproductive rates grow slowly. Such organisms can be categorized as *K*-strategists, which tend to persist at or near the carrying capacity of the environment. They are adapted to predictable environments, and they tend to be more specialized in their resource use, and less tolerant of variation in resource quality, than other organisms. They produce few offspring, but each offspring has a high probability of surviving to adulthood. Recall that the number of births in a population tends to be highest when that population is well below its carrying capacity. For large, long-lived species that we wish to harvest, we should manage the population so that it is far enough below the carrying capacity to have a high birth rate. But some species (such as whales) reproduce so slowly that they cannot sustain any kind of substantial harvest rate. Short-lived organisms with high reproductive rates can be categorized as *r*-strategists. These organisms can generally use a wide variety of resources and tolerate a wide range of conditions, and they can produce large numbers of offspring when conditions are suitable. If we wish to decrease the numbers of a short-lived, rapidly reproducing pest species (such as rats), killing individuals will only increase the birth rate. A better approach is to reduce the species' resources (e.g., clean up garbage) in order to decrease the carrying capacity for the species. In each case, of course, managers need to understand the specific life history and population dynamics of the species they wish to manage.
8. Humans are subject to the same population dynamics that other species are. Resource abundance is a density-dependent population-regulating factor. Like the reindeer population on St. Matthew, the Irish population crashed when its food supply was diminished. Three kinds of changes in the rates of demographic events contributed to the decrease in population size. Recall that $N_1 = N_0 + (B - D) + (I - E)$. First, the emigration rate (E) increased. Second, the age at first reproduction, and thus generation time, increased, so the birth rate (B) decreased. In other words, the population's life history traits changed with changing environmental conditions. Finally, as a direct effect of the food shortage, the death rate (D) increased. A look at the social history of the Irish potato famine might tell us more about the roles of the Irish population's own growth before the famine and whether intraspecific competition (discussed further in Chapter 56) was involved in regulating the food supply—whether other populations monopolized resources and limited the access of the Irish people to those resources.
9. Those who support the view that biological controls should not be used under any circumstances might cite the example of the cane toad in Australia, which not only failed to control the cane beetles it was introduced to control but became a serious pest in its own right. They might note that many species introduced into new regions, where their normal predators and pathogens are absent, reach population densities much higher than those in their native ranges, and they might argue that there is no reason to think this generality would not apply to species introduced as biological control agents. Those who support the view that biological controls can be used safely and effectively might cite the example of the successful control of the cottony-cushion scale in California, which was brought under control within a year by the introduction of a predaceous ladybeetle and a parasitic fly. They might also argue that horror stories like that of the cane toad could be avoided by proper study of the ecology of the proposed biological control agents before they are introduced. Studies in test plots prior to release almost certainly would have revealed that Australian cane beetles stay high on the upper stalks of cane plants, out of reach of the toads, and studies of the toads' life histories might have revealed their generalized and voracious appetites. Strict requirements for extensive testing for specificity and efficacy prior to release can greatly reduce the risk that biological control agents themselves will become pests after they are introduced. But opponents of biological control might respond that, because natural systems are so complex, even careful study might fail to reveal the real risks of introducing a particular species into a new environment.

10. Corridors have to be defined in terms of specific organisms and their dispersal abilities. Corridors consist of habitat between patches through which the organisms of interest can move. An area that serves as a corridor for birds might not be effective as a corridor for small arthropods. On the other hand, the small arthropods would need less habitat area to maintain a viable population. Thus, designing a single study to determine the effects of corridors would be very difficult. A single experiment might be able to determine effects of corridors on animals that are similar in size and mobility but not if organisms differ widely in those attributes. To understand the effects of corridors in fragmented habitats, it is very important to consider multiple organisms because organisms interact within these habitats. Investigators in the Palenque National Park in Mexico discovered that birds are more likely to be recaptured in home forest patches connected by corridors to the patches where they were released than in home forest patches unconnected to the patches where they were released. However, their ability to navigate these corridors successfully depends on the presence of other species, including predators, and their ability to survive in home patches depends on the presence of other species, including prey species, as well. Designing a single study to determine the effects of corridors would be very difficult.

CHAPTER 56

1. a 2. c 3. c 4. d 5. e
6. The interactions among ants, cacti, and pollinators described in the Working With Data exercise represent a diversity of types of interactions. By fending off potential herbivores, the pugnacious ant bodyguards act as mutualists of the cactus, as do the bee species that visit the flowers and serve as pollinators. The five ant species all appear to use the extrafloral nectaries on this plant in similar ways and thus may be competitors for extrafloral nectar. Each type of interaction depends on the relative abundance and activities of the interacting species. Cactus plants that grow where there are no herbivorous insects may have no need of pugnacious bodyguards; under those circumstances, the ants might be considered parasites for removing extrafloral nectar without providing any defensive services. The mutualism between ants and plants could also break down if bee pollinators are scarce and the most aggressive ant bodyguard prevents any bees at all from pollinating the flowers.
7. Which pine trees are susceptible to mountain pine beetle attack could be determined by direct observation and by experimentation. Within infested stands, investigators may be able to identify individual pine trees that do not harbor beetle populations and characterize properties that may make them resistant to the beetles (e.g., ability to produce large quantities of resin). Conversely, trees with especially high beetle populations might have properties that make them particularly susceptible (having a history of surviving fire or lightning strike). Experiments can also be conducted under controlled conditions, in which investigators test various species to determine if beetles display a preference for particular species. The fact that this beetle has a symbiotic partner upon which it depends in order to feed on pine trees suggests that a novel strategy for managing the outbreak could be to identify a fungicide that kills the symbiont, thereby rendering the beetle incapable of colonizing and killing the trees. Although there are no such programs currently in use today, many researchers are exploring this dimension of interaction ecology to devise novel methods for pest management.
8. (a) By establishing a microbial population that excludes undesirable species, the poultry industry is applying the principle of competitive exclusion. The principle states that two or more species utilizing a limited resource in similar ways cannot coexist. In the broiler chicks given a culture of three species of bacteria, a microbial community was established in which introduced *Salmonella* could not compete.
- (b) Other ecological outcomes this experiment might have produced include ultimate domination of the gut flora by only one species of bacterium or coexistence of all four bacterial species. Whether these species coexist or whether one or more species goes extinct depends on the availability of resources in the chicken intestines.
- (c) The principle of competitive exclusion might be useful in tackling other problems involving a community of organisms growing under confined conditions. This ecological principle provides part of the rationale for the use of probiotics by humans to improve a variety of conditions. Probiotics are live organisms that are consumed in food for health benefits, which are thought to accrue by altering the microbial balance, inhibiting the growth of deleterious species. Probiotics are being investigated for treatment of intestinal inflammatory diseases, pathogen-related diarrhea, and infections of the urogenital tract.
9. If parasites and their hosts coevolve, then the phylogenetic relationships among parasites should reflect the phylogenetic relationships among the hosts. DNA analysis revealed that flamingoes are actually more closely related to grebes than they are to ducks and geese. This relationship leads to the prediction that lice on flamingoes should be more closely related to the lice on grebes than they are to the lice on ducks and geese. Modern methods of molecular analysis that can be used to determine relationships among bird lice and their

hosts include constructing a DNA-based phylogeny of multiple species of waterbirds and their lice and then comparing the phylogenies of the hosts and parasites to see if they are congruent (see Chapter 22). In addition to acquiring parasites by shared ancestry between hosts and parasites, bird species may also acquire parasites by virtue of the fact that they share habitats and come in contact with other bird species, each of which has its own parasite fauna. Because flamingoes, ducks, grebes, and geese are all waterbirds, the possibility exists that flamingoes may have acquired some of its louse parasites by this process of host switching.

10. Among the requirements for a mutualistic pollination system is behavior by the pollinator that ensures it will visit more than one individual of the same plant species. Visiting more than one individual provides a pollinator with the opportunity to carry pollen from one plant individual to the receptive stigmatic surface of another individual of the same species. A pollinator that encounters a feeding deterrent that limits the amount of nectar it can imbibe in a single visit is more likely to continue foraging for nectar on another plant individual. The process of taking a larger number of smaller meals by seeking nectar from flowers of different plant individuals increases the likelihood that the pollinator will carry pollen from one individual to another. Too much nicotine in nectar, however, may reduce the likelihood of pollination if it deters future visits to conspecifics altogether or if it impairs the behavior of its pollinator (nicotine is a neurotoxin). Another factor limiting the amount of nicotine is the cost to the plant of biosynthesizing the compound; investing in increased amounts of nicotine may leave fewer resources to invest in producing flowers, seeds and fruits.

CHAPTER 57

1. a 2. a 3. b 4. d 5. a 6. c 7. e
8. The diversity of microbes in the human gut can be compared between individuals or across populations by using the same methods employed for comparing diversity of macroscopic communities. Diversity encompasses both the number of different species present, and richness, or abundances of individuals across species. To determine which microbes might be keystone species, selective antibiotics can be used to eliminate particular species and the effects of that elimination on community composition then monitored. Applying the methods for assessing diversity that were developed for macroscopic communities to assessing diversity for microbial communities is limited, however, by our ability to isolate, identify, and quantify all of the microbial species present. Although molecular methods of identifying microbial species has vastly expanded this capacity, there remain challenges in recognizing and categorizing the full expanse of microbial diversity.
9. According to the theory of island biogeography, the number of species on an island represents a balance between the rate at which species immigrate to and colonize the island and the rate at which resident species go locally extinct. With increasing distance from a source pool, the equilibrium number of species on an island decreases; with increasing size of an island, the species number increases. The pattern of hawk moth diversity documented by Beck and Hitchling in the 113 islands of Thailand and mainland Malaysia conforms to several of the predictions of island biogeography. The continental source of colonists includes over 180 species. Borneo, a large island close to Thailand, has a larger number of species (between 113 and 135) than does New Guinea (with 46 to 90 species), which is roughly comparable in size and farther away from Thailand. Generally speaking, too, the prediction that larger islands support higher numbers of species is also upheld; Borneo has a larger number of species than the much smaller Philippines (between 46 and 112 species), even though the two places are about equidistant from Thailand.
10. The pattern documented by Marek Sammul, Lauri Oksanen, and M. Magi—that removal of one perennial species from plant communities resulted in an increase in biomass of its competitors in highly productive communities—has been documented in other communities. One hypothesis postulates that interspecific competition becomes more intense when productivity is very high. Goldenrod (*Solidago virgaurea*) is apparently a superior competitor that, when present in a community, can suppress other species. In less productive communities, competition is less intense, so release from competition with goldenrod does not result in increased growth of any remaining species. The results of this study parallel those of a long-term experiment at the Rothamsted Experiment Station in England, in which fertilizer added regularly to selected plots of land to increase their productivity resulted in a decline in the number of plant species compared with the other plots in the study that were unfertilized; in these less productive, unfertilized plots, species diversity remained essentially the same. An alternative hypothesis could be that goldenrod inhibits the growth of co-occurring plant species (as some colonizing species do in early stages of succession). This hypothesis could be tested directly by extracting root exudates of goldenrod and testing their ability to inhibit germination and growth of other species in the community.
11. Whether lampreys should be eliminated as damaging parasites of game fish, or encouraged as ecosystem engineers that create nesting sites that might increase the reproductive success of game fish depends on many factors. Some of the factors are ecological; it is important to quantify the impact of existing

A-16 Answers to Chapter Review Questions

sea lamprey populations on survivorship of game fish as well as to estimate the lamprey population size that does not influence survivorship. As well, the beneficial impact of nutrient enrichment and provisioning of nesting habitat should be measured. In addition, designing an ecologically sound lamprey management strategy will also require consideration of local cultural values; assessments of the economic value of the sport fishing industry to the local community and the aesthetic and cultural value placed by the local community on maintaining a more natural assemblage of fish species should be made and factored into management plans.

CHAPTER 58

1. e 2. d 3. c 4. c 5. a 6. b

7. The rate of turnover would be important to the recovery rate of a lake, and that would depend on its location. In Lake Washington, which is located in a temperate climate, turnover would occur every spring and fall. When sewage was flowing into the lake, the nutrients it contained would have led to eutrophication and thus to oxygen depletion in the bottom water. Once the flow of sewage stopped, however, biomass production would have decreased. There would have been fewer dead organisms to sink to the lake bottom, less accumulation of nutrients on the lake bottom, and less oxygen-consuming decomposition there. Fall and spring turnover would have brought the accumulated nutrients to the lake surface and oxygen to the bottom, improving conditions for organisms that were typical of the lake's preindustrial community. If the lake had been located in a climate where seasonal temperature changes were not great enough to cause turnover, the excess nutrients that had accumulated would have remained on the lake bottom, and eutrophic conditions would have persisted much longer. It's also possible that other conditions in the area might affect the lake's recovery time. Acid precipitation, for example, can affect the viability of freshwater organisms, and, if it were a problem in the region, it might slow the lake community's recovery.

8. A local effect might be nitrogen deposition. Coal—an organic fossil fuel—contains nitrogen, and its combustion would release nitrogen compounds (such as nitrogen dioxide, NO_2 , and nitrous oxide, N_2O) through the smokestacks into the atmosphere. Some of this nitrogen would fall back to land in precipitation or as dry particles. The resulting increase of nitrogen in the soil would favor those plant species that are best adapted to take advantage of high nutrient levels, which would then outcompete other species. Thus the composition of the plant community would change and species diversity would be likely to decrease. Nitrogen deposition might also contribute to eutrophication in lakes, and emission of nitrogen into the atmosphere would contribute to smog.

A regional effect might be acid precipitation. The combustion of fossil fuels releases NO_2 and sulfur dioxide (SO_2) into the atmosphere; both compounds react with water molecules in the atmosphere to form nitric acid (HNO_3) and sulfuric acid (H_2SO_4), respectively. These acids can travel hundreds of kilometers in the atmosphere, so their emission would affect ecosystems far from the smokestacks. Acid precipitation can damage the leaves of plants and reduce their rate of photosynthesis, and it can reduce fish and invertebrate species richness in freshwater lakes.

A global effect would be climate change. The combustion of fossil fuels releases large amounts of CO_2 , as well as lesser amounts of N_2O —both greenhouse gases. The presence of N_2O in the atmosphere also results in the production of tropospheric ozone; it, too, acts as a greenhouse gas as well as contributing to smog. The increasing concentrations of greenhouse gases in the atmosphere are already resulting in global climate warming. This climate change is having a number of worrisome effects on the global ecosystem, such as the shrinking of Arctic sea ice, rising sea level and potential coastal flooding, and profound changes in the abundances and distributions of species.

The SO_2 released when coal is burned not only produces acid rain, but also contributes to global warming. Scrubbers remove the SO_2 , but the scrubbing process contributes to pollution in another form—the process generates solid waste byproducts that contain sulfur, which must be deposited in a landfill, along with other solid waste products generated by burning coal.

9. Iron (Fe) is needed by organisms in only small amounts, but it is nevertheless an essential micronutrient. It is scarce in ocean waters because it is insoluble in oxygenated water, so that iron that enters the oceans sinks rapidly to the seafloor. The experiment described in the text demonstrated that iron is a limiting nutrient in the oceans: when the investigators added dissolved iron to surface waters in the equatorial Pacific Ocean, the large phytoplankton bloom that resulted was accompanied by an increase in the uptake of nitrate and carbon dioxide, showing that these nutrients had been available but underused. This experiment showed that adding iron to ocean waters increased photosynthesis, but to better understand the effects of iron fertilization, more such experiments would have to be carried out, still on an ecosystem scale, but over a longer time span. Investigators would have to observe the effects of the iron increase on the entire food web. The fertilized ecosystem would have to be compared with an unfertilized control ecosystem far enough away from the experimental one that the added iron, and its effects, would not reach it.

10. If the “cap and trade” system worked as intended, it could put the brakes on the ongoing increases quickly, holding emissions to the level that prevailed when the law went into effect. It might also be more acceptable to polluters than an outright ban on or regulation of emissions. And it might encourage some companies to invest more in cleaner technology, since doing so might give them credits to sell, or at least spare them having to buy credits. The drawbacks might include the likelihood that the government would have to set up a system to administer and enforce the law. They also include the fact that it is not easy to pass such a law (the United States, for example, has not succeeded in doing so). The biggest polluters might be reluctant to increase their costs of doing business by paying for credits and might thus be likely to lobby against such a law. From a different viewpoint, environmentalists might argue that a cap and trade system is an inadequate response to global warming—that we must not only stop increases in emissions, but decrease them dramatically. They might also argue that there is a moral hazard in allowing anyone to “pay to pollute”—that it might legitimize pollution.

11. No one hurricane—or even several—can be ascribed to global warming. Remember the difference between weather and climate, described in Chapter 54: “Weather is the short-term state of atmospheric conditions at a particular place and time, whereas climate refers to the average atmospheric conditions, and the extent of their variation, at a particular place over a longer time. In other words, climate is what you expect; weather is what you get.” But neither does the observation that hurricanes have occurred for many centuries show that the climate has *not* changed. To address this question, we would have to compile temperature and hurricane data over long periods. First, we would have to show that the average temperatures of ocean waters are increasing over time—which has been done. Second, we would have to show that warmer water is correlated with more or stronger hurricanes—that there have been more and stronger hurricanes during years, or longer periods, when the water was warmer than in periods when it was cooler. Such a correlation would supply evidence that warming of the oceans is increasing hurricane frequency and intensity. It is more difficult to demonstrate that the warming of ocean waters is caused by increasing concentrations of greenhouse gases in the atmosphere, but most scientists believe that the evidence supports that claim.

CHAPTER 59

1. b 2. e 3. e 4. a 5. d 6. c 7. b

8. Conservation biologists and others who wish to preserve biodiversity are usually working with limited resources, so they often face hard choices. They might choose to focus their efforts in biodiversity hotspots and centers of imminent extinction, but within those areas, they would face many other choices. When we discussed the principles of island biogeography, we described the species-area relationship: large islands can support a larger equilibrium number of species than small islands. The same is true of “habitat islands.” Protected areas often act as habitat islands, as many are surrounded by habitat that has been made unsuitable for many species by human activities. We must also consider edge effects, keeping in mind that not all of the area we protect will actually remain suitable habitat for communities and species of interest. Therefore, if we wish to preserve natural communities with their full diversity, the larger the preserved area, the better. However, if our concern is focused on one or a few endangered species, we may wish to preserve several separated areas of habitat; that way, if a disturbance or disease should wipe out the population in one area, the entire species will not become extinct. The area or areas we choose, however, must be large enough for the species to maintain a viable population in order to avoid loss of genetic variation. We might favor areas where corridors could be maintained to allow individuals to disperse from the protected area or areas and maintain other populations. But it is rare that a protected area can be designed based on these criteria alone; the plans are also dependent on the willingness of landowners, governments, and area residents to support the preservation of the area.

9. Some might argue that if the sheep constitute only a single population, but there are other populations of pumas, that the puma should be removed from the sheep's range. However, if the puma is a keystone predator in the region, removing it might have unforeseen negative consequences for other species in the community—recall the example of wolves in Yellowstone National Park, described in Chapter 57. If neither the sheep nor the puma is an introduced species—that is, if predator and prey had survived together for a long time before becoming threatened—it might be worth taking a look at what has changed. Have the sheep experienced a loss of habitat or resources, so that their populations are now too small to withstand the rate of predation that they once did? Those observations might suggest an alternative to suppressing the puma population: Could former sheep habitat be restored so that a larger sheep population could be supported, or as a last resort, could the sheep be bred in captivity and then introduced to a new, puma-free area?

10. To some extent, international organizations already have a triage system of sorts in place. The International Union for the Conservation of Nature (IUCN), e.g., divides species in imminent danger of extinction in all or most of

their range as “endangered” or “critically endangered”, differentiating them from those who are less likely to go extinct in the near future (and thus are classified as “vulnerable”). To some degree, this classification system can result in prioritization of rescue efforts. One problem with applying the triage system of World War I to species conservation, however, is that medical science is far more successful at predicting the certainty of death than ecological science is at predicting the certainty of extinction. After all, medical science is focused on one species, which has been the subject of intense scrutiny beginning in the

earliest days of scientific research. The cost of erring in assigning certainty to extinction is the loss of an entire species—a unique combination of genes that, at least with current technology, can never be reconstructed.

11. Opinion as to the extent to which ethical and moral arguments should enter into discussions of protecting biodiversity varies widely. Your answer might take into consideration a wide range of cultural, historical, and economic factors, as well as the considerations brought to bear by modern scientific knowledge.

Glossary

A

A horizon See topsoil.

abiotic (a' bye ah tick) [Gk. *a*: not + *bios*: life] Nonliving. (Contrast with biotic.)

abomasum The true stomach of a ruminant.

abortion Any termination of pregnancy, whether induced or natural (in which case it is called a spontaneous abortion), that occurs after a fertilized egg is successfully implanted in the uterus.

abscisic acid (ABA) (ab sighs' ik) A plant growth substance with growth-inhibiting action. Causes stomata to close; involved in a plant's response to salt and drought stress.

abscission (ab sizh' un) [L. *abscissio*: break off] The process by which leaves, petals, and fruits separate from a plant.

absorption (1) Of light: complete retention, without reflection or transmission. (2) Of water or other molecules: soaking up (taking in through pores or by diffusion).

absorption spectrum A graph of light absorption versus wavelength of light; shows how much light is absorbed at each wavelength.

absorptive heterotrophs Organisms (primarily fungi) that feed by **absorptive heterotrophy**, i.e., by secreting digestive enzymes into the environment to break down large food molecules, then absorbing the breakdown products.

absorptive state State in which food is in the gut and nutrients are being absorbed. (Contrast with postabsorptive state.)

abyssal zone (uh biss' ul) [Gk. *abyssos*: bottomless] The deepest parts of the ocean.

accessory pigments Pigments that absorb light and transfer energy to chlorophylls for photosynthesis.

accessory sex organs Anatomical structures that allow transfer of sperm from male to female for internal fertilization. (contrast with primary sex organs.)

acclimation, acclimatization Acclimation refers to increased tolerance for environmental extremes (e.g., extreme cold) after prior exposure to them. Acclimatization refers to intrinsic seasonal adjustments in the "set points" of an animal's physiological functioning (e.g., metabolic rate).

acetyl coenzyme A (acetyl CoA) A compound that reacts with oxaloacetate to

produce citrate at the beginning of the citric acid cycle; a key metabolic intermediate in the formation of many compounds.

acetylcholine (ACh) A neurotransmitter that carries information across vertebrate neuromuscular junctions and some other synapses. It is then broken down by the enzyme acetylcholinesterase (AChE).

acid [L. *acidus*: sharp, sour] A substance that can release a proton in solution. (Contrast with base.)

acid growth hypothesis The hypothesis that auxin increases proton pumping, thereby lowering the pH of the cell wall and activating enzymes that loosen polysaccharides. Proposed to explain auxin-induced cell expansion in plants.

acid precipitation Precipitation that has a lower pH than normal as a result of acid-forming precursor molecules introduced into the atmosphere by human activities.

acidic Having a pH below 7.0 (i.e., a hydrogen ion concentration greater than 10^{-7} molar). (Contrast with basic.)

acoelomate An animal that does not have a coelom.

acrosome (a' krow soam) [Gk. *akros*: highest + *soma*: body] The structure at the forward tip of an animal sperm which is the first to fuse with the egg membrane and enter the egg cell.

ACTH See corticotropin.

actin [Gk. *aktis*: ray] A protein that makes up the cytoskeletal microfilaments in eukaryotic cells and is one of the two contractile proteins in muscle. See also myosin.

action potentials Generated by neurons, these are electrical signals that transmit information via waves of depolarization or hyperpolarization of the cell membrane.

action spectrum A graph of a biological process versus light wavelength; shows which wavelengths are involved in the process.

activation energy (E_a) The energy barrier that blocks the tendency for a chemical reaction to occur.

activator A transcription factor that stimulates transcription when it binds to a gene's promoter. (Contrast with repressor.)

active site The region on the surface of an enzyme or ribozyme where the substrate binds, and where catalysis occurs.

active transport The energy-dependent transport of a substance across a biological membrane against a concentration gradient—that is, from a region of low concentration (of that substance) to one of high concentration. (See also primary active transport, secondary active transport; contrast with facilitated diffusion, passive transport.)

adaptation (a dap tay' shun) (1) In evolutionary biology, a particular structure, physiological process, or behavior that makes an organism better able to survive and reproduce. Also, the evolutionary process that leads to the development or persistence of such a trait. (2) In sensory neurophysiology, a sensory cell's loss of sensitivity as a result of repeated stimulation.

adaptive defenses One of the two general types of defenses against pathogens. Involves antibody proteins and other proteins that recognize, bind to, and aid in the destruction of specific viruses and bacteria. Present only in vertebrate animals. (Contrast with innate defenses.)

adaptive radiation A series of evolutionary events that results in an array (radiation) of related species that live in a variety of environments, differing in the characteristics each uses to exploit those environments.

additive growth Population growth in which a constant number of individuals is added to the population during successive time intervals. (Contrast with multiplicative growth.)

adenine (A) (a' den een) A nitrogen-containing base found in nucleic acids, ATP, NAD, and other compounds.

adenosine triphosphate See ATP.

adrenal gland (a dreé' nal) [L. *ad*: toward + *renes*: kidneys] An endocrine gland located near the kidneys of vertebrates, consisting of two parts, the **adrenal cortex** and **adrenal medulla**.

adrenaline See epinephrine.

adrenergic receptors G protein-linked receptor proteins that bind to the hormones epinephrine and norepinephrine, triggering specific responses in the target cells.

adrenocorticotrophic hormone (ACTH) See corticotropin.

adsorption Binding of a gas or a solute to the surface of a solid.

G-2 Glossary

adventitious roots (ad ven ti' shus) [L. *adventitius*: arriving from outside] Roots originating from the stem at ground level or below; typical of the fibrous root system of monocots.

aerenchyma In plants, parenchymal tissue containing air spaces.

aerobic (air oh' bic) [Gk. *aer*: air + *bios*: life] In the presence of oxygen; requiring or using oxygen (as in **aerobic metabolism**). (Contrast with anaerobic.)

afferent (af' ur unt) [L. *ad*: toward + *ferre*: to carry] Carrying to, as in neurons that carries impulses to the central nervous system (**afferent neurons**), or a blood vessel that carries blood to a structure. (Contrast with efferent.)

age structure The distribution of the individuals in a population across all age groups.

agonist A chemical substance (e.g., a neurotransmitter) that elicits a specific response in a cell or tissue. (Contrast with antagonist.)

air sacs Structures in the respiratory system of birds that receive inhaled air; they keep fresh air flowing unidirectionally through the lungs, but are not themselves gas exchange surfaces.

alcoholic fermentation See fermentation.

aldosterone (al dohs' ter own) A steroid hormone produced in the adrenal cortex of mammals. Promotes secretion of potassium and reabsorption of sodium in the kidney.

aleurone layer In some seeds, a tissue that lies beneath the seed coat and surrounds the endosperm. Secretes digestive enzymes that break down macromolecules stored in the endosperm.

allantoic membrane In animal development, an outgrowth of extraembryonic endoderm plus adjacent mesoderm that forms the allantois, a saclike structure that stores metabolic wastes produced by the embryo.

allantois (al' lun toh is) [Gk. *allant*: sausage] An extraembryonic membrane enclosing a sausage-shaped sac that stores the embryo's nitrogenous wastes.

allele (a leel') [Gk. *allos*: other] The alternate form of a genetic character found at a given locus on a chromosome.

allele frequency The relative proportion of a particular allele in a specific population.

allergic reaction [Ger. *allergie*: altered] An overreaction of the immune system to amounts of an antigen that do not affect most people; often involves IgE antibodies.

allopatric speciation (al' lo pat' rick) [Gk. *allos*: other + *patria*: homeland] The formation of two species from one when reproductive isolation occurs because of the interposition of (or crossing of) a physical geographic barrier such as a river. Also called geographic speciation. (Contrast with sympatric speciation.)

allopolyploidy The possession of more than two chromosome sets that are derived from more than one species.

allosteric regulation (al lo steer' ik) [Gk. *allos*: other + *stereos*: structure] Regulation of the activity of a protein (usually an enzyme) by the binding of an effector molecule to a site other than the active site.

α (alpha) helix A prevalent type of secondary protein structure; a right-handed spiral.

alternation of generations The succession of multicellular haploid and diploid phases in some sexually reproducing organisms, notably plants.

alternative splicing A process for generating different mature mRNAs from a single gene by splicing together different sets of exons during RNA processing.

altruistic Pertaining to behavior that benefits other individuals at a cost to the individual who performs it.

alveolus (al ve' o lus) (plural: alveoli) [L. *alveus*: cavity] A small, baglike cavity, especially the blind sacs of the lung.

amensalism (a men' sul ism) Interaction in which one animal is harmed and the other is unaffected. (Contrast with commensalism, mutualism.)

amine An organic compound containing an amino group (NH_2).

amine hormones Small hormone molecules synthesized from single amino acids (e.g., thyroxine and epinephrine).

amino acid An organic compound containing both NH_2 and COOH groups. Proteins are polymers of amino acids.

amino acid replacement A change in the nucleotide sequence that results in one amino acid being replaced by another.

ammonia NH_3 , the most common nitrogenous waste.

ammonotelic (am moan' o teal' ic) [Gk. *telos*: end] Pertaining to an organism in which the final product of breakdown of nitrogen-containing compounds (primarily proteins) is **ammonia**. (Contrast with ureotelic, uricotelic.)

amnion (am' nee on) The fluid-filled sac within which the embryos of reptiles (including birds) and mammals develop.

amniote egg A shelled egg surrounding four extraembryonic membranes and embryo-nourishing yolk. This evolutionary adaptation permitted mammals and reptiles to live and reproduce in drier environments than can most amphibians.

amphipathic (am' fi path' ic) [Gk. *amphi*: both + *pathos*: emotion] Of a molecule, having both hydrophilic and hydrophobic regions.

amplitude The magnitude of change over the course of a regular cycle.

amygdala A component of the limbic system that is involved in fear and the memory of fearful experiences.

amylase (am' ill ase) An enzyme that catalyzes the hydrolysis of starch, usually to maltose or glucose.

anabolic reaction (an uh bah' lik) [Gk. *ana*: upward + *ballein*: to throw] A synthetic reaction in which simple molecules are linked to form more complex ones; requires an input of energy and captures it in the chemical bonds that are formed. (Contrast with catabolic reaction.)

anaerobic (an ur row' bic) [Gk. *an*: not + *aer*: air + *bios*: life] Occurring without the use of molecular oxygen, O_2 . (Contrast with aerobic.)

anaphase (an' a phase) [Gk. *ana*: upward] The stage in cell nuclear division at which the first separation of sister chromatids (or, in the first meiotic division, of paired homologs) occurs.

ancestral trait The trait originally present in the ancestor of a given group; may be retained or changed in the descendants of that ancestor.

androgen (an' dro jen) Any of the several male sex steroids (most notably testosterone).

aneuploidy (an' you ploy dee) A condition in which one or more chromosomes or pieces of chromosomes are either lacking or present in excess.

angiosperms Flowering plants; one of the two major groups of living seed plants. (See also gymnosperms.)

angiotensin (an' jee oh ten' sin) A peptide hormone that raises blood pressure by causing peripheral vessels to constrict. Also maintains glomerular filtration by constricting efferent vessels and stimulates thirst and the release of aldosterone.

angular gyrus A part of the human brain believed to be essential for integrating spoken and written language.

animal hemisphere The metabolically active upper portion of some animal eggs, zygotes, and embryos; does not contain the dense nutrient yolk. (Contrast with vegetal hemisphere.)

anion (an' eye on) [Gk. *ana*: upward] A negatively charged ion. (Contrast with cation.)

annual A plant whose life cycle is completed in one growing season. (Contrast with biennial, perennial.)

antagonist A biochemical (e.g., a drug) that blocks the normal action of another biochemical substance.

antagonist interactions Interactions between two species in which one species benefits and the other is harmed. Includes predation, herbivory, and parasitism.

antenna system See light-harvesting complex.

anterior Toward or pertaining to the tip or headward region of the body axis. (Contrast with posterior.)

anterior pituitary The portion of the vertebrate pituitary gland that derives from gut epithelium. Produces trophic hormones.

anther (an' thur) [Gk. *anthos*: flower] A pollen-bearing portion of the stamen of a flower.

antheridium (an' thur id' ee um) [Gk. *antheros*: blooming] The multicellular structure that produces the sperm in nonvascular land plants and ferns.

antibody One of the myriad proteins produced by the immune system that specifically binds to a foreign substance in blood or other tissue fluids and initiates its removal from the body.

anticodon The three nucleotides in transfer RNA that pair with a complementary triplet (a codon) in messenger RNA.

antidiuretic hormone (ADH) See vasopressin

antigen (an' ti jun) Any substance that stimulates the production of an antibody or antibodies in the body of a vertebrate.

antigen-presenting cell In cellular immunity, a cell that ingests and digests an antigen, and then exposes fragments of that antigen to the outside of the cell, bound to proteins in the cell's plasma membrane.

antigenic determinant The specific region of an antigen that is recognized and bound by a specific antibody. Also called an epitope.

antiparallel Pertaining to molecular orientation in which a molecule or parts of a molecule have opposing directions.

antiporter A membrane transport protein that moves one substance in one direction and another in the opposite direction. (Contrast with symporter, uniporter.)

antisense RNA A single-stranded RNA molecule complementary to, and thus targeted against, an mRNA of interest to block its translation.

anus (a' nus) An opening through which solid digestive wastes are expelled, located at the posterior end of a tubular gut.

aorta (a or' tah) [Gk. *aorte*: aorta] The main trunk of the arteries leading to the systemic (as opposed to the pulmonary) circulation.

aortic body A chemosensor in the aorta that senses a decrease in blood supply or a dramatic decrease in partial pressure of oxygen in the blood.

aortic valve A one-way valve between the left ventricle of the heart and the aorta that prevents backflow of blood into the ventricle when it relaxes.

apex (a' pecks) The tip or highest point of a structure, as of a growing stem or root.

aphasia a deficit in the ability to use or understand words.

aphotic zone In bodies of water (lakes and oceans), the region below the reach of light.

apical dominance In plants, inhibition by the apical bud of the growth of axillary buds.

apical hook A form taken by the stems of many eudicot seedlings that protects the delicate shoot apex while the stem grows through the soil.

apical meristem The meristem at the tip of a shoot or root; responsible for a plant's primary growth.

apomixis (ap oh mix' is) [Gk. *apo*: away from + *mixis*: sexual intercourse] The asexual production of seeds.

apoplast (ap' oh plast) In plants, the continuous meshwork of cell walls and extracellular spaces through which material can pass without crossing a plasma membrane. (Contrast with symplast.)

apoptosis (ap uh toh' sis) A series of genetically programmed events leading to cell death.

aposematism Warning coloration; bright colors or striking patterns of toxic or toxin-mimic species that act as a warning to predators.

appendix In the human digestive system, the vestigial equivalent of the cecum (blind pouc), which serves no digestive function.

aquaporin A transport protein in plant and animal cell membranes through which water passes in osmosis.

aquatic (a kwa' tic) [L. *aqua*: water] Pertaining to or living in water. (Contrast with marine, terrestrial.)

aqueous (a' kwee us) Pertaining to water or a watery solution.

aquifer A large pool of groundwater.

archegonium (ar' ke go' nee um) The multicellular structure that produces eggs in nonvascular land plants, ferns, and gymnosperms.

archenteron (ark en' ter on) [Gk. *archos*: first + *enteron*: bowel] The earliest primordial animal digestive tract.

area phylogeny Phylogenetic tree in which the names of the taxa are replaced with the names of the places where those taxa live or lived.

arms race A series of reciprocal adaptations between species involved in antagonistic interactions, in which adaptations that increase the fitness of a consumer species exert selection pressure on its resource species to counter the consumer's adaptation, and vice versa.

arteriole A small blood vessel arising from an artery that feeds blood into a capillary bed.

artery A muscular blood vessel carrying oxygenated blood away from the heart to other parts of the body. (Contrast with vein.)

artificial insemination An infertility treatment that involves the artificial introduction of sperm into the woman's reproductive tract.

artificial selection The selection by human plant and animal breeders of individuals with certain desirable traits.

ascus (ass' cus) (plural: asci) [Gk. *askos*: bladder] In sac fungi, the club-shaped sporangium within which spores (ascospores) are produced by meiosis.

asexual reproduction Reproduction without sex.

assisted reproductive technologies

(ARTs) Any of several procedures that remove unfertilized eggs from the ovary, combine them with sperm outside the body, and then place fertilized eggs or egg-sperm mixtures in the appropriate location in a female's reproductive tract for development.

association cortex In the vertebrate brain, the portion of the cortex involved in higher-order information processing, so named because it integrates, or associates, information from different sensory modalities and from memory.

associative learning A form of learning in which two unrelated stimuli become linked to the same response.

asthenosphere (ass thenn' o sphere) [Gk. *asthenes*: weak] The viscous, malleable (changeable) layer of Earth's mantle. It is overlain by the solid lithospheric plates.

astrocyte [Gk. *astron*: star] A type of glial cell that contributes to the blood-brain barrier by surrounding the smallest, most permeable blood vessels in the brain.

atherosclerosis (ath' er oh sklair oh' sis) [Gk. *athero*: gruel, porridge + *skleros*: hard] A disease of the lining of the arteries characterized by fatty, cholesterol-rich deposits in the walls of the arteries. When fibroblasts infiltrate these deposits and calcium precipitates in them, the disease becomes arteriosclerosis, or "hardening of the arteries."

atom [Gk. *atomos*: indivisible] The smallest unit of a chemical element. Consists of a nucleus and one or more electrons.

atomic mass See atomic weight.

atomic number The number of protons in the nucleus of an atom; also equals the number of electrons around the neutral atom. Determines the chemical properties of the atom.

atomic weight The average of the mass numbers of a representative sample of atoms of an element, with all the isotopes in their normally occurring proportions. Also called atomic mass.

ATP (adenosine triphosphate) An energy-storage compound containing adenine, ribose, and three phosphate groups. When it is formed from ADP, useful energy is stored; when it is broken down (to ADP or AMP), energy is released to drive endergonic reactions.

ATP synthase An integral membrane protein that couples the transport of protons with the formation of ATP.

atrial natriuretic peptide A hormone released by the atrial muscle fibers of the heart when they are overly stretched, which decreases reabsorption of sodium by the kidney and thus blood volume.

atrioventricular node A modified node of cardiac muscle that organizes the action potentials that control contraction of the ventricles.

atrium (a' tree um) [L. *atrium*: central hall] An internal chamber. In the hearts of

G-4 Glossary

vertebrates, the thin-walled chamber(s) entered by blood on its way to the ventricle(s). Also, the outer ear.

auditory system A sensory system that uses mechanoreceptors to convert pressure waves into receptor potentials; includes structures that gather sound waves, direct them to a sensory organ, and amplify their effect on the mechanoreceptors.

autocatalysis [Gk. *autos*: self + *kata*: to break down] A positive feedback process in which an activated enzyme acts on other inactive molecules of the same enzyme to activate them.

autocrine A chemical signal that binds to and affects the cell that makes it. (Contrast with paracrine.)

autoimmune diseases Diseases (e.g., rheumatoid arthritis) that result from failure of the immune system to distinguish between self and nonself, causing it to attack tissues in the organism's own body.

autoimmunity An immune response by an organism to its own molecules or cells.

autonomic nervous system (ANS) The portion of the peripheral nervous system that controls such involuntary functions as those of guts and glands. Also called the involuntary nervous system.

autophagy The programmed destruction of a cell's components.

autopolyploidy The possession of more than two entire chromosomes sets that are derived from a single species.

autoregulatory mechanisms In mammalian circulatory systems, local control of blood flow through capillary beds by constriction or dilation of incoming arterioles in response to local metabolite concentrations.

autosome Any chromosome (in a eukaryote) other than a sex chromosome.

autotroph (au' tow trowf) [Gk. *autos*: self + *trophe*: food] An organism that is capable of living exclusively on inorganic materials, water, and some energy source such as sunlight (photoautotrophs) or chemically reduced matter (see chemoautotrophs). (Contrast with heterotroph.)

auxin (awk' sin) [Gk. *auxein*: to grow] In plants, a substance (the most common being indoleacetic acid) that regulates growth and various aspects of development.

avirulence (Avr) genes Genes in a pathogen that may trigger defenses in plants. See gene-for-gene resistance.

Avogadro's number The number of atoms or molecules in a mole (weighed out in grams) of a substance, calculated to be 6.023×10^{23} .

axillary bud A bud that forms in the angle (axil) where a leaf meets a stem.

axon [Gk. *axle*] The process (branching structure) of a neuron that conducts action potentials away from the cell body. See also dendrites.

axon hillock The junction between an axon and the neuron's cell body; where action potentials are generated.

axon terminal The end portion of an axon, which passes action potentials to another cell. Axon terminals can form synapses and release neurotransmitter.

B

B cell A type of lymphocyte involved in the humoral immune response of vertebrates. Upon recognizing an antigenic determinant, a B cell develops into a plasma cell, which secretes an antibody. (Contrast with T cell.)

B horizon See subsoil.

bacillus (bah sil' us) [L: little rod] Any of various rod-shaped bacteria.

bacterial conjugation See conjugation.

bacteriophage (bak teer' ee o fayi) [Gk. *bakterion*: little rod + *phagein*: to eat] Any of a group of viruses that infect bacteria. Also called phage.

bacteroids Nitrogen-fixing organelles that develop from endosymbiotic bacteria.

bark All tissues external to the vascular cambium of a plant.

barometric pressure Atmospheric pressure; the total pressure of the gas mixture in air.

baroreceptor [Gk. *baros*: weight] A pressure-sensing cell or organ. Sometimes called a stress receptor.

basal metabolic rate (BMR) The minimum rate of energy turnover in an awake (but resting) bird or mammal that is not expending energy for thermoregulation.

base (1) A substance that can accept a hydrogen ion in solution. (Contrast with acid.) (2) In nucleic acids, the purine or pyrimidine that is attached to each sugar in the sugar-phosphate backbone.

base pair (bp) In double-stranded DNA, a pair of nucleotides formed by the complementary base pairing of a purine on one strand and a pyrimidine on the other. (See complementary base pairing.)

basic Having a pH greater than 7.0 (i.e., having a hydrogen ion concentration lower than 10^{-7} molar). (Contrast with acidic.)

basidioma (plural: basiomata) A fruiting structure produced by club fungi.

basidium (bass id' ee yum) In club fungi, the characteristic sporangium in which four **basidiospores** are formed by meiosis and then borne externally before being shed.

basilar membrane A membrane in the human inner ear whose flexion in response to sound waves activates hair cells; flexes at different locations in response to different pitch.

Batesian mimicry The convergence in appearance of an edible species (mimic) with an unpalatable species (model).

behavioral ecology An evolutionary approach to the study of animal behavior that studies how behaviors are adaptive in different environmental conditions.

behaviorism One of two classical approaches to the study of proximate

causes of animal behavior, derived from the discoveries of Ivan Pavlov and focused on laboratory studies. (Compare with ethology.)

benefit Improvement in survival and reproductive success resulting from performing a behavior or having a trait.

benthic zone [Gk. *benthos*: bottom] The bottom of the ocean.

β (beta) pleated sheet A type of protein secondary structure; results from hydrogen bonding between polypeptide regions running antiparallel to each other.

biased gene conversion A mechanism of concerted evolution in which a DNA repair system appears biased in favor of using particular nucleotide sequences as templates for repair, resulting in the rapid spread of the favored sequence across all copies of the gene. (See concerted evolution.)

bicarbonate ion Ion (HCO_3^-) resulting from dissociation of carbonic acid in water; important in pH regulation and carbon dioxide (CO_2) transport.

biennial A plant whose life cycle includes vegetative growth in the first year and flowering and senescence in the second year. (Contrast with annual, perennial.)

bilateral symmetry The condition in which only the right and left sides of an organism, divided by a single plane through the midline, are mirror images of each other.

bilayer A structure that is two layers in thickness. In biology, most often refers to the phospholipid bilayer of membranes. (See phospholipid bilayer.)

bile A secretion of the liver made up of bile salts synthesized from cholesterol, various phospholipids, and bilirubin (the breakdown product of hemoglobin). Emulsifies fats in the small intestine.

binary fission Reproduction of a prokaryote by division of a cell into two comparable progeny cells.

binocular vision Overlapping visual fields of an animal's two eyes; allows the animal to see in three dimensions.

binomial nomenclature A taxonomic naming system in which each species is given a binomial (Gk.: two names), a genus name followed by a species name.

biodiversity hotspots Regions identified by conservation biologists as being particularly in need of protection because they harbor great species richness and endemism (i.e., large numbers of species, many of which are found nowhere else).

biofilm A community of microorganisms embedded in a polysaccharide matrix, forming a highly resistant coating on almost any moist surface.

biogeochemical cycle Movement of inorganic elements such as nitrogen, phosphorus, and carbon through living organisms and the physical environment.

biogeographic region One of several defined, continental-scale regions of Earth,

each of which has a biota distinct from that of the others. (Contrast with biome.)

biogeography The scientific study of the patterns of distribution of populations, species, and ecological communities across Earth.

bioinformatics The use of computers and/or mathematics to analyze complex biological information, such as DNA sequences.

biological control The use of natural enemies (predators, parasites, or pathogens) to reduce the population density of an economically damaging (pest) species.

biological species concept The definition of a species as a group of actually or potentially interbreeding natural populations that are reproductively isolated from other such groups. (Contrast with lineage species concept; morphological species concept.)

biology [Gk. *bios*: life + *logos*: study] The scientific study of living things.

bioluminescence The production of light by biochemical processes in an organism.

biome (bye' ome) A major division of the ecological communities of Earth, characterized primarily by distinctive vegetation. A given biogeographic region contains many different biomes.

bioremediation The use by humans of other organisms to remove contaminants from the environment.

biosphere (bye' oh sphere) All regions of Earth (terrestrial and aquatic) and Earth's atmosphere in which organisms can live.

biota (bye oh' tah) All of the organisms—animals, plants, fungi, and microorganisms—found in a given area. (Contrast with flora, fauna.)

biotechnology The use of living cells or organisms to produce materials useful to humans.

biotic (bye ah' tick) [Gk. *bios*: life] Alive. (Contrast with abiotic.)

biotic interchange The mixing of biotas previously separated by physical, climatic, or other barriers, for example when two formerly separated land masses fuse.

blastocoel (blass' toe seal) [Gk. *blastos*: sprout + *koilos*: hollow] The central, hollow cavity of a blastula.

blastocyst (blass' toe cist) An early embryo formed by the first divisions of the fertilized egg (zygote). In mammals, a hollow ball of cells.

blastodisc (blass' toe disk) An embryo that forms as a disk of cells on the surface of a large yolk mass; comparable to a blastula, but occurring in animals such as birds and reptiles, in which the massive yolk restricts complete cleavage.

blastomere Any of the cells produced by the early divisions of a fertilized animal egg.

blastopore The opening created by the invagination of the vegetal pole during gastrulation of animal embryos.

blastula (blass' chu luh) An early stage of the animal embryo; in many species, a hollow sphere of cells surrounding a central cavity, the blastocoel. (Contrast with blastodisc.)

block to polyspermy Any of several responses to entry of a sperm into an egg that prevent more than one sperm from entering the egg.

blood A fluid connective tissue that is pumped throughout the body. A component of the circulatory system, blood transports gases such as oxygen and carbon dioxide as well as other essential elements.

blood clotting A cascade of events involving platelets and circulating proteins (clotting factors) that seals damaged blood vessels.

blood-brain barrier The selective impermeability of blood vessels in the brain that prevents most chemicals from diffusing from the blood into the brain.

blue-light receptors Pigments in plants that absorb blue light (400–500 nm). These pigments mediate many plant responses including photo-tropism, stomatal movements, and expression of some genes.

body plan The general structure of an animal, the arrangement of its organ systems, and the integrated functioning of its parts.

Bohr effect A shift in the O₂ binding curve of hemoglobin in response to excess H⁺ ions such that the hemoglobin releases more O₂ in tissues where pH is low.

Bohr model A model for atomic structure that depicts the atom as largely empty space, with a central nucleus surrounded by electrons in orbits, or electron shells, at various distances from the nucleus.

bond See chemical bond.

bone A rigid component of vertebrate skeletal systems that contains an extracellular matrix of insoluble calcium phosphate crystals as well as collagen fibers.

Bowman's capsule An elaboration of the renal tubule, composed of podocytes, that surrounds and collects the filtrate from the glomerulus.

brain The centralized integrative center of a nervous system.

brainstem The portion of the vertebrate brain between the spinal cord and the forebrain, made up of the medulla, pons, and midbrain.

brassinosteroids Plant steroid hormones that mediate light effects promoting the elongation of stems and pollen tubes.

Broca's area A portion of the human brain essential for speech. Located in the frontal lobe just in front of the primary motor cortex.

bronchioles The smallest airways in a vertebrate lung, branching off the bronchi.

bronchus (plural: bronchi) The major airway(s) branching off the trachea into the vertebrate lung.

brown fat In mammals, fat tissue that is specialized to produce heat. It has many

mitochondria and capillaries, and a protein that uncouples oxidative phosphorylation.

budding Asexual reproduction in which a more or less complete new organism grows from the body of the parent organism, eventually detaching itself.

buffer A substance that can transiently accept or release hydrogen ions and thereby resist changes in pH.

bulbourethral glands Secretory structures of the human male reproductive system that produce a small volume of an alkaline, mucoid secretion that helps neutralize acidity in the urethra and lubricate it to facilitate the passage of semen.

bulk flow The movement of a solution from a region of higher pressure potential to a region of lower pressure potential.

bundle of His Fibers of modified cardiac muscle that conduct action potentials from the atria to the ventricular muscle mass.

bundle sheath cell Part of a tissue that surrounds the veins of plants.

C

C horizon See parent rock.

C₃ plants Plants that produce 3PG as the first stable product of carbon fixation in photosynthesis and use ribulose biphosphate as a CO₂ receptor.

C₄ plants Plants that produce oxaloacetate as the first stable product of carbon fixation in photosynthesis and use phosphoenolpyruvate as CO₂ acceptor. C₄ plants also perform the reactions of C₃ photosynthesis.

calcitonin Hormone produced by the thyroid gland; lowers blood calcium and promotes bone formation. (Contrast with parathyroid hormone.)

calcitriol A hormone derived from vitamin D whose actions include stimulating the cells of the digestive tract to absorb calcium from ingested food.

calorie [L. *calor*: heat] The amount of heat required to raise the temperature of 1 gram of water by 1°C. Physiologists commonly use the kilocalorie (kcal) as a unit of measure (1 kcal = 1,000 calories). Nutritionists also use the kilocalorie, but refer to it as the **Calorie** (capital C).

Calvin cycle The stage of photosynthesis in which CO₂ reacts with RuBP to form 3PG, 3PG is reduced to a sugar, and RuBP is regenerated, while other products are released to the rest of the plant. Also known as the Calvin-Benson cycle.

calyx (kay' licks) [Gk. *kalyx*: cup] All of the sepals of a flower, collectively.

CAM See crassulacean acid metabolism.

Cambrian explosion The rapid diversification of multicellular life that took place during the Cambrian period.

cAMP (cyclic AMP) A compound formed from ATP that acts as a second messenger.

cancellous bone A type of bone with numerous internal cavities that make it

G-6 Glossary

appear spongy, although it is rigid. (Contrast with compact bone.)

canopy The leaf-bearing part of a tree. Collectively, the aggregate of the leaves and branches of the larger woody plants of an ecological community.

capillaries [L. *capillaris*: hair] Very small tubes, especially the smallest blood-carrying vessels of animals between the termination of the arteries and the beginnings of the veins.

Capillary beds are networks of capillaries where materials are exchanged between the blood and the interstitial fluid.

capsid The outer shell of a virus that encloses its nucleic acid.

carbohydrates Organic compounds containing carbon, hydrogen, and oxygen in the ratio 1:2:1 (i.e., with the general formula $C_nH_{2n}O_n$). Common examples are sugars, starch, and cellulose.

carbon skeleton The chains or rings of carbon atoms that form the structural basis of organic molecules. Other atoms or functional groups are attached to the carbon atoms.

carbon-fixation reactions The phase of photosynthesis in which chemical energy captured in the light reactions is used to drive the reduction of CO_2 to form carbohydrates.

carboxylase An enzyme that catalyzes the addition of carboxyl functional groups ($O=C-OH$) to a substrate.

cardiac cycle Contraction of the two atria of the heart, followed by contraction of the two ventricles and then relaxation.

cardiac muscle A type of muscle tissue that makes up, and is responsible for the beating of, the heart. Characterized by branching cells with single nuclei and a striated (striped) appearance. (Contrast with smooth muscle, skeletal muscle.)

cardiovascular system [Gk. *kardia*: heart + L. *vasculum*: small vessel] The heart, blood, and vessels are of a circulatory system.

carnivore [L. *carn*: flesh + *vorare*: to devour] An organism that eats animal tissues. (Contrast with detritivore, frugivore, herbivore, omnivore.)

carotenoid (ka rah' tuh noid) A yellow, orange, or red lipid pigment commonly found as an accessory pigment in photosynthesis; also found in fungi.

carotid body A chemosensor in the carotid artery that senses a decrease in blood supply or a dramatic decrease in partial pressure of oxygen in the blood.

carpel (kar' pel) [Gk. *karpos*: fruit] The organ of the flower that contains one or more ovules.

carrier (1) In facilitated diffusion, a membrane protein that binds a specific molecule and transports it through the membrane. (2) In respiratory and photosynthetic electron transport, a participating substance such as NAD that exists in both oxidized and reduced forms. (3) In genetics, a person heterozygous for a recessive trait.

carrying capacity (K) The maximum number of individuals in a population (i.e., maximum population size) that can be supported by the resources present in a given environment.

cartilage In vertebrates, a tough connective tissue found in joints, the outer ear, and elsewhere. Forms the entire skeleton in some animal groups.

cartilage bone A type of bone that begins its development as a cartilaginous structure resembling the future mature bone, then gradually hardens into mature bone. (Contrast with membranous bone.)

Casparian strip A band of cell wall containing suberin and lignin, found in the endodermis. Restricts the movement of water across the endodermis.

caspase One of a group of proteases that catalyze cleavage of target proteins and are active in apoptosis.

catabolic reaction (kat uh bah' lik) [Gk. *kata*: to break down + *ballein*: to throw] A synthetic reaction in which complex molecules are broken down into simpler ones and energy is released. (Contrast with anabolic reaction.)

catabolite repression In the presence of abundant glucose, the diminished synthesis of catabolic enzymes for other energy sources.

catalyst (kat' a list) [Gk. *kata*: to break down] A chemical substance that accelerates a reaction without itself being consumed in the overall course of the reaction. Catalysts lower the activation energy of a reaction. Enzymes are biological catalysts.

cation (cat' eye on) An ion with one or more positive charges. (Contrast with anion.)

caudal [L. *cauda*: tail] Pertaining to the tail, or to the posterior part of the body.

cDNA See complementary DNA.

cDNA library A collection of complementary DNAs derived from mRNAs of a particular tissue at a particular time in the life cycle of an organism.

cecum (see' cum) [L. blind] A blind branch off the large intestine. In many nonruminant mammals, the cecum contains a colony of microorganisms that contribute to the digestion of food.

cell The simplest structural unit of a living organism. In multicellular organisms, many individual cells serve as the building blocks of tissues and organs.

cell adhesion molecules (CAMs)

Molecules on animal cell surfaces that affect the selective association of cells into tissues during development of the embryo. Also a component of desmosomes.

cell cycle The stages through which a cell passes between one mitotic division and the next. Includes all stages of interphase and mitosis. (See mitosis.)

cell cycle checkpoints Points of transition between different phases of the cell cycle, which are regulated by cyclins and cyclin-dependent kinases (Cdks).

cell division The reproduction of a cell to produce two new cells. In eukaryotes, this process involves nuclear division (mitosis) and cytoplasmic division (cytokinesis).

cell fate The type of cell that an undifferentiated cell in an embryo will become in the adult.

cell junctions Specialized structures associated with the plasma membranes of epithelial cells. Some contribute to cell adhesion, others to intercellular communication.

cell potency In multicellular organisms, an undifferentiated cell's potential to become a cell of a specific type. (See multipotent; pluripotent; totipotent.)

cell recognition Binding of cells to one another mediated by membrane proteins or carbohydrates.

cell theory States that cells are the basic structural and physiological units of all living organisms, and that all cells come from preexisting cells.

cell wall A relatively rigid structure that encloses cells of plants, fungi, many protists, and most prokaryotes, and which gives these cells their shape and limits their expansion in hypotonic media.

cellular immune response Immune system response mediated by T cells and directed against parasites, fungi, intracellular viruses, and foreign tissues (grafts). (Contrast with humoral immune response.)

cellular respiration The catabolic pathways by which electrons are removed from various molecules and passed through intermediate electron carriers to O_2 , generating H_2O and releasing energy.

cellular specialization In multicellular organisms, the division of labor such that different cell types become responsible for different functions (e.g., reproduction or digestion) within the organism.

cellulose (sell' you lowss) A straight-chain polymer of glucose molecules, used by plants as a structural supporting material.

central dogma The premise that information flows from DNA to RNA to polypeptide (protein).

central nervous system (CNS) That portion of the nervous system that is the site of most information processing, storage, and retrieval; in vertebrates, the brain and spinal cord. (Contrast with peripheral nervous system.)

central vacuole In plant cells, a large organelle that stores the waste products of metabolism and maintains turgor.

centrifuge [L. *centrum*: center + *fugere*: to flee] A laboratory device in which a sample is spun around a central axis at high speed. Used to separate suspended materials of different densities.

centriole (sen' tree ole) A paired organelle that helps organize the microtubules in animal and protist cells during nuclear division.

centromere (sen' tro meer) [Gk. *centron*: center + *meros*: part] The region where sister chromatids join.

centrosome (sen' tro soam) The major microtubule organizing center of an animal cell.

cephalization (sef ah luh zay' shun) [Gk. *kephale*: head] The evolutionary trend toward increasing concentration of brain and sensory organs at the anterior end of the animal.

cerebellum (sair uh bell' um) [L. diminutive of *cerebrum*, brain] The brain region that controls muscular coordination; located at the anterior end of the hindbrain.

cerebral cortex The thin layer of gray matter (neuronal cell bodies) that overlies the cerebrum.

cerebrum (su ree' brum) [L. brain] The dorsal anterior portion of the forebrain, making up the largest part of the brain of mammals; the chief coordination center of the nervous system and the major information-processing areas of the vertebrate brain consists of two **cerebral hemispheres**.

cervix (sir' vix) [L. neck] The opening of the uterus into the vagina.

cGMP (cyclic guanosine monophosphate) An intracellular messenger that is part of signal transmission pathways involving G proteins. (See G protein.)

channel protein An integral membrane protein that forms an aqueous passageway across the membrane in which it is inserted and through which specific solutes may pass.

chaperone A protein that guards other proteins by counteracting molecular interactions that threaten their three-dimensional structure.

character In genetics, an observable feature, such as eye color. (Contrast with trait.)

character displacement An evolutionary phenomenon in which species that compete for the same resources within the same territory tend to diverge in morphology and/or behavior.

chemical bond An attractive force stably linking two atoms.

chemical equilibrium See equilibrium

chemical evolution The theory that life originated through the chemical transformation of inanimate substances.

chemical reaction The change in the composition or distribution of atoms of a substance with consequent alterations in properties.

chemical synapse Neural junction at which neurotransmitter molecules released from a presynaptic cell induce changes in a postsynaptic cell. (Contrast with electrical synapse.)

chemically gated channel A type of membrane channel that opens or closes depending on the presence or absence of a specific molecule that binds either to the channel protein itself or to a separate receptor

that alters the three-dimensional shape of the channel protein.

chemiosmosis Formation of ATP in mitochondria and chloroplasts, resulting from a pumping of protons across a membrane (against a gradient of electrical charge and of pH), followed by the return of the protons through a protein channel with ATP synthase activity.

chemoautotroph Organisms that obtain energy by oxidizing inorganic substances, using some of that energy to fix carbon. Also known as chemolithotrophs.

chemoheterotroph An organism that must obtain both carbon and energy from organic substances. (Contrast with chemoautotroph, photoautotroph, photoheterotroph.)

chemoreceptor A sensory receptor cell that senses specific molecules (such as odorant molecules or pheromones) in the environment.

chiasma (kie az' muh) (plural: chiasmata) [Gk. cross] An X-shaped connection between paired homologous chromosomes in prophase I of meiosis. A chiasma is the visible manifestation of crossing over between homologous chromosomes.

chief cells One of three types of secretory cell found in the gastric pits of the stomach wall. Chief cells secrete the protein-digesting enzyme pepsin. (See mucosal epithelium; parietal cells.)

chitin (kye' tin) [Gk. *kiton*: tunic] The characteristic tough but flexible organic component of the exoskeleton of arthropods, consisting of a complex, nitrogen-containing polysaccharide. Also found in cell walls of fungi.

chlorophyll (klor' o fill) [Gk. *kloros*: green + *phyllon*: leaf] Any of several green pigments associated with chloroplasts or with certain bacterial membranes; responsible for trapping light energy for photosynthesis.

chloroplast [Gk. *kloros*: green + *plast*: a particle] An organelle bounded by a double membrane containing the enzymes and pigments that perform photosynthesis. Chloroplasts occur only in eukaryotes.

choanocyte (ko' an uh site) The collared, flagellated feeding cells of sponges.

cholecystokinin (CCK) (ko' luh sis tuh kai' nin) A hormone produced and released by the lining of the duodenum when it is stimulated by undigested fats and proteins. It stimulates the gallbladder to release bile and slows stomach activity.

chorion (kor' ee on) [Gk. *khorian*: afterbirth] The outermost of the membranes protecting mammal, bird, and reptile embryos; in mammals it forms part of the placenta.

chromatid (kro' ma tid) A newly replicated chromosome, from the time molecular duplication occurs until the time the centromeres separate (during anaphase of mitosis or of meiosis II).

chromatin The nucleic acid-protein complex that makes up eukaryotic chromosomes.

chromatin remodeling A mechanism for epigenetic gene regulation by the alteration of chromatin structure.

chromosomal mutation Loss of or changes in position/direction of a DNA segment on a chromosome.

chromosome (krome' o sowm) [Gk. *kroma*: color + *soma*: body] In bacteria and viruses, the DNA molecule that contains most or all of the genetic information of the cell or virus. In eukaryotes, a structure composed of DNA and proteins that bears part of the genetic information of the cell.

chylomicron (ky low my' cron) Particles of lipid coated with protein, produced in the gut from dietary fats and secreted into the extracellular fluids.

chyme (kime) [Gk. *kymus*: juice] Created in the stomach; a mixture of ingested food with the digestive juices secreted by the salivary glands and the stomach lining.

cilia (sil' ee ah) (singular: cilium) [L. eyelashes] Hairlike organelle used for locomotion by many unicellular organisms and for moving water and mucus by many multicellular organisms. Generally shorter than flagella.

circadian rhythm (sir kade' ee an) [L. *circa*: approximately + *dies*: day] A rhythm of growth or activity that recurs about every 24 hours.

circannual rhythm [L. *circa*: + *annus*: year] A rhythm of growth or activity that recurs on a yearly basis.

circulatory system A physiological system consisting of a muscular pump (heart), a fluid (blood or hemolymph), and a series of conduits (blood vessels) that transports materials around the body.

11-cis-retinal The nonprotein, light-absorbing component of the visual pigment rhodopsin. (See rhodopsin.)

cis-trans isomers In molecules with a double bond (typically between two carbon atoms), identifies on which side of the double bond similar atoms or functional groups are found. If they are on the same side, the molecule is a *cis* isomer; in a *trans* isomer, similar atoms are on opposite sides of the double bond. (See isomer.)

citric acid cycle In cellular respiration, a set of chemical reactions whereby acetyl CoA is oxidized to carbon dioxide and hydrogen atoms are stored as NADH and FADH₂. Also called the Krebs cycle.

clade [Gk. *klados*: branch] A monophyletic group made up of an ancestor and all of its descendants.

class I MHC molecules Cell surface proteins that participate in the cellular immune response directed against virus-infected cells.

class II MHC molecules Cell surface proteins that participate in the cell-cell interactions (of T-helper cells, macrophages, and B cells) of the humoral immune response.

class switching Occurs when a B cell changes the immunoglobulin class it synthesizes (e.g., a B cell making IgM switches to making IgG).

cleavage The first few cell divisions of an animal zygote. *See also* complete cleavage, incomplete cleavage.

climate The long-term average atmospheric conditions (temperature, precipitation, humidity, wind direction and velocity) found in a region. (Contrast with weather.)

climax community The final stage of succession; a community that is capable of perpetuating itself under local climatic and soil conditions and persists for a relatively long time.

clinal variation [Gk. *klinein*: to lean] Gradual change in the phenotype of a species over a geographic gradient.

cloaca The opening through which both urinary wastes and digestive wastes are expelled in most amphibians and in reptiles (including birds).

clonal deletion Inactivation or destruction of lymphocyte clones that would produce immune reactions against the animal's own body.

clonal lineages Asexually reproduced groups of nearly identical organisms.

clonal selection Mechanism by which exposure to antigen results in the activation of selected T- or B-cell clones, resulting in an immune response.

clone [Gk. *klon*: twig, shoot] (1) Genetically identical cells or organisms produced from a common ancestor by asexual means. (2) To produce many identical copies of a DNA sequence by its introduction into, and subsequent asexual reproduction of, a cell or organism.

closed circulatory system Circulatory system in which the circulating fluid is contained within a continuous system of vessels. (Contrast with open circulatory system.)

clumped dispersion pattern *See* dispersion

CO (CONSTANS) Gene coding for a transcription factor that activates the synthesis of florigen (FT); involved in the induction of flowering.

co-repressor In the regulation of bacterial operons, a molecule that binds to the repressor, causing it to change shape and bind to the operator, thereby inhibiting transcription.

coastal zone The marine life zone that extends from the shoreline to the edge of the continental shelf. Characterized by relatively shallow, well-oxygenated water and relatively stable temperatures and salinities.

coccus (kock' us) (plural: cocci) [Gk. *kokkos*: berry, pit] Any of various spherical or spheroidal bacteria.

cochlea (kock' lee uh) [Gk. *kokhlos*: snail] A spiral tube in the inner ear of vertebrates; it contains the sensory cells involved in hearing.

codominance A condition in which two alleles at a locus produce different phenotypic effects and both effects appear in heterozygotes.

codon Three nucleotides in messenger RNA that direct the placement of a particular amino acid into a polypeptide chain. (Contrast with anticodon.)

coelom (see' loam) [Gk. *koiloma*: cavity] An animal body cavity, enclosed by muscular mesoderm and lined with a mesodermal layer called peritoneum that also surrounds the internal organs.

coelomate Possessing a coelom.

coenocytic (seen' a sit ik) [Gk. *koinos*: common + *kytos*: container] Referring to the condition, found in some fungal hyphae, of "cells" containing many nuclei but enclosed by a single plasma membrane. Results from nuclear division without cytokinesis.

coenzyme A nonprotein organic molecule that plays a role in catalysis by an enzyme.

coenzyme A (CoA) A coenzyme used in various biochemical reactions as a carrier of acyl groups.

coevolution Evolutionary processes in which an adaptation in one species leads to the evolution of an adaptation in a species with which it interacts; also known as reciprocal adaptation.

cofactor An inorganic ion that is weakly bound to an enzyme and required for its activity.

cohesin A protein involved in binding chromatids together.

cohesion The tendency of molecules (or any substances) to stick together.

cohort (co' hort) [L. *cohors*: company of soldiers] A group of similar-aged organisms.

cold-hardening A process by which plants can acclimate to cooler temperatures; requires repeated exposure to cool temperatures over many days.

coleoptile A sheath that surrounds and protects the shoot apical meristem and young primary leaves of a grass seedling as they move through the soil.

collagen [Gk. *kolla*: glue] A fibrous protein found extensively in bone and connective tissue.

collecting duct In vertebrates, a tubule that receives urine produced in the nephrons of the kidney and delivers that fluid to the ureter for excretion.

collenchyma (cull eng' kyma) [Gk. *kolla*: glue + *enchyma*: infusion] A type of plant cell, living at functional maturity, which lends flexible support by virtue of primary cell walls thickened at the corners. (Contrast with parenchyma, sclerenchyma.)

colon [Gk. *kolon*] The portion of the gut between the small intestine and the anus. Also called the large intestine.

commensalism [L. *com*: together + *mensa*: table] A type of interaction between species in

which one participant benefits while the other is unaffected.

communication A signal from one organism (or cell) that alters the functioning or behavior of another organism (or cell).

community Any ecologically integrated group of species of microorganisms, plants, and animals inhabiting a given area.

compact bone A type of bone with a solid, hard structure. (Contrast with cancellous bone.)

companion cell In angiosperms, a specialized cell found adjacent to a sieve tube element.

comparative experiment Experimental design in which data from various unmanipulated samples or populations are compared, but in which variables are not controlled or even necessarily identified. (Contrast with controlled experiment.)

comparative genomics Computer-aided comparison of DNA sequences between different organisms to reveal genes with related functions.

competition In ecology, use of the same resource by two or more species when the resource is present in insufficient supply for the combined needs of the species.

competitive exclusion A result of competition between species for resources, in which one species completely eliminates the other from a given habitat.

competitive inhibitor A nonsubstrate that binds to the active site of an enzyme and thereby inhibits binding of its substrate. (Contrast with noncompetitive inhibitor.)

complement system A group of eleven proteins that play a role in some reactions of the immune system. The complement proteins are not immunoglobulins.

complementary base pairing The AT (or AU), TA (or UA), CG, and GC pairing of bases in double-stranded DNA, in transcription, and between tRNA and mRNA.

complementary DNA (cDNA) DNA formed by reverse transcriptase acting with an RNA template; essential intermediate in the reproduction of retroviruses; used as a tool in recombinant DNA technology; lacks introns.

complete cleavage Pattern of cleavage that occurs in eggs that have little yolk. Early cleavage furrows divide the egg completely and the blastomeres are of similar size. (Contrast with incomplete cleavage.)

complete metamorphosis A change of state during the life cycle of an organism in which the body is almost completely rebuilt to produce an individual with a very different body form. Characteristic of insects such as butterflies, moths, beetles, ants, wasps, and flies.

complex ions Groups of covalently bonded atoms that carry an electric charge (e.g., NH_4^+ , the ammonium ion).

complex life cycle In reference to parasitic species, a life cycle that requires more than one host to complete.

composite transposon Two transposable elements located near one another that transpose together and carry the intervening DNA sequence with them. (See transposable element.)

compound (1) A substance made up of atoms of more than one element. (2) Made up of many units, as in the **compound eyes** of arthropods.

concentration gradient A difference in concentration of an ion or other chemical substance from one location to another, often across a membrane. (See active transport; facilitated diffusion.)

concerted evolution The common evolution of a family of repeated genes, such that changes in one copy of the gene family are replicated in other copies of the gene family, and thus evolve “in concert.” (See biased gene conversion; unequal crossing over.)

condensation reaction A chemical reaction in which two molecules become connected by a covalent bond and a molecule of water is released ($AH + BOH \rightarrow AB + H_2O$). (Contrast with hydrolysis reaction.)

conditional mutation A mutation that results in a characteristic phenotype only under certain environmental conditions.

conditioned reflex A form of associative learning first described by Ivan Pavlov, in which a natural response (such as salivation in response to food) becomes associated with a normally unrelated stimulus (such as the sound of a bell).

conduction The transfer of heat from one object to another through direct contact.

cone In conifers, a reproductive structure consisting of spore-bearing scales extending from a central axis. (Contrast with strobilus.)

cone cell In the vertebrate retina, a type of photoreceptor cell responsible for color vision.

conidium (ko nid' ee um) (plural: conidia) [Gk. *konis*: dust] A type of haploid fungal spore borne at the tips of hyphae, not enclosed in sporangia.

conjugation (kon ju gay' shun) [L. *conjugare*: yoke together] (1) A process by which DNA is passed from one cell to another through a conjugation tube, as in bacteria. (2) A nonreproductive sexual process by which *Paramecium* and other ciliates exchange genetic material.

connective tissue A type of tissue that connects or surrounds other tissues; its cells are embedded in a collagen-containing matrix. One of the four major tissue types in multicellular animals, including cartilage, bone, blood, and fat.

connexon In a gap junction, a protein channel linking adjacent animal cells.

conservation biology An applied science that carries out investigations with the aim of maintaining the diversity of life on Earth.

conserved Pertaining to a gene or trait that has evolved very slowly and is similar or even identical in individuals of highly divergent groups.

conspecifics Individuals of the same species.

constant region The portion of an immunoglobulin molecule whose amino acid composition determines its class and does not vary among immunoglobulins in that class. (Contrast with variable region.)

constitutive Always present; produced continually at a constant rate. (Contrast with inducible.)

constitutive genes Genes that are expressed all the time. (Contrast with inducible genes.)

constitutive proteins Proteins that an organism produces all the time, and at a relatively constant rate.

consumer An organism that eats the tissues of some other organism.

consumer-resource interactions Interactions in which organisms gain their nutrition by eating other living organisms or are eaten themselves.

continental drift The gradual movements of the world's continents that have occurred over billions of years.

contraception Birth control methods that prevent fertilization or implantation (conception).

contractile vacuole (kon trak' tul) A specialized vacuole that collects excess water taken in by osmosis, then contracts to expel the water from the cell.

controlled experiment An experiment in which a sample is divided into groups whereby experimental groups are exposed to manipulations of an independent variable while one group serves as an untreated control. The data from the various groups are then compared to see if there are changes in a dependent variable as a result of the experimental manipulation. (Contrast with comparative experiment.)

controlled system A set of components in a physiological system that is controlled by commands from a regulatory system. (Contrast with regulatory system.)

convection The transfer of heat to or from a surface via a moving stream of air or fluid.

convergent evolution Independent evolution of similar features from different ancestral traits.

convolutions Foldings of the vertebrate brain's cerebral cortex into ridges called gyri (sing. **gyrus**) and valleys called sulci (sing. **sulcus**). The level of cortical convolution increases taxonomically and is especially extensive in humans.

copulation Reproductive behavior that results in a male depositing sperm in the reproductive tract of a female.

cork cambium [L. *cambiare*: to exchange] In plants, a lateral meristem that produces secondary growth, mainly in the form of waxy-walled protective cells, including some of the cells that become bark.

cork In plants, a protective outermost tissue layer composed of cells with thick walls waterproofed with suberin.

cornea The clear, transparent tissue that covers the eye and allows light to pass through to the retina.

corolla (ko role' lah) [L. *corolla*: a small crown] All of the petals of a flower, collectively.

corpus luteum (kor' pus loo' tee um) (plural: corpora lutea) [L. yellow body] A structure formed from a follicle after ovulation; produces hormones important to the maintenance of pregnancy.

corridor A connection between habitat patches through which organisms can disperse; plays a critical role in maintaining subpopulations.

cortex [L. *cortex*: covering, rind] (1) In plants, the tissue between the epidermis and the vascular tissue of a stem or root. (2) In animals, the outer tissue of certain organs, such as the adrenal gland (adrenal cortex) and the brain (cerebral cortex).

corticosteroids Steroid hormones produced and released by the cortex of the adrenal gland.

corticotropin A tropic hormone produced by the anterior pituitary hormone that stimulates cortisol release from the adrenal cortex. Also called adrenocorticotrophic hormone (ACTH).

corticotropin-releasing hormone A hormone produced by the hypothalamus that controls the release of cortisol from the anterior pituitary.

cortisol A corticosteroid that mediates stress responses.

cost A decrease in fitness resulting from performing a behavior or having a trait.

cost-benefit approach An approach to evolutionary studies that assumes an animal has a limited amount of time and energy to devote to each of its activities, and that each activity has fitness costs as well as benefits. (See also trade-off.)

cotyledon (kot' ul lee' dun) [Gk. *kotyledon*: hollow space] A “seed leaf.” An embryonic organ that stores and digests reserve materials; may expand when seed germinates.

countercurrent flow An arrangement that promotes the maximum exchange of heat, or of a diffusible substance, between two fluids by having the fluids flow in opposite directions through parallel vessels close together.

countercurrent heat exchanger In “hot” fish, an adaptation of the circulatory system such that arterial blood flowing into the muscles is warmed by venous blood flowing

out of the muscles, thereby conserving body heat by countercurrent exchange.

countercurrent multiplier The mechanism that increases the concentration of the interstitial fluid in the mammalian kidney through countercurrent flow in the loops of Henle and selective permeability and active transport of ions by segments of the loops of Henle.

covalent bond Chemical bond based on the sharing of electrons between two atoms.

CpG islands DNA regions rich in C residues adjacent to G residues. Especially abundant in promoters, these regions are where methylation of cytosine usually occurs.

crassulacean acid metabolism (CAM) A metabolic pathway enabling the plants that possess it to store carbon dioxide at night and then perform photosynthesis during the day with stomata closed.

critical night length In the photoperiodic flowering response of short-day plants, the length of night above which flowering occurs and below which the plant remains vegetative. (The reverse applies in the case of long-day plants.)

critical period See sensitive period.

crop A simple food storage sac, the first of two stomachlike organs in many animals (including reptiles, earthworms, and various insects). (See also gizzard.)

cross section A section taken perpendicular to the longest axis of a structure. Also called a transverse section.

crossing over The mechanism by which linked genes undergo recombination. In general, the term refers to the reciprocal exchange of corresponding segments between two homologous chromatids.

crosstalk Interactions between different signal transduction pathways.

cryptis [Gk. *kryptos*: hidden] The resemblance of an organism to some part of its environment, which helps it to escape detection by enemies.

cryptochromes [Gk. *kryptos*: hidden + *kroma*: color] Photoreceptors mediating some blue-light effects in plants and animals.

ctene (teen) [Gk. *cteis*: comb] In ctenophores, a comblike row of cilia-bearing plates. Ctenophores move by beating the cilia on their eight ctenes.

culture (1) A laboratory association of organisms under controlled conditions. (2) The collection of knowledge, tools, values, and rules that characterize a human society.

cumulus A thick gelatinous layer that protects a mammalian ovum.

cupula Gelatinous swelling in the semicircular canals of the vestibular system. A cupula encloses hair cell stereocilia that react to shifting fluid in the canal ducts.

currents Circulation patterns in the surface waters of oceans driven by the prevailing winds.

cuticle (1) In plants, a waxy layer on the outer body surface that retards water loss. (2) In ecdysozoans, an outer body covering that provides protection and support and is periodically molted.

cyclic AMP See cAMP.

cyclic electron transport In photosynthetic light reactions, the flow of electrons that produces ATP but no NADPH or O₂.

cyclical succession Pattern of change in community composition (succession) in which the climax community depends on periodic disturbances (e.g., fire) in order to persist. (Contrast with directional succession.)

cyclin A protein that activates a cyclin-dependent kinase, bringing about transitions in the cell cycle.

cyclin-dependent kinase (Cdk) A protein kinase whose target proteins are involved in transitions in the cell cycle and which is active only when complexed with additional protein subunits, called cyclins.

cytokine A regulatory protein made by immune system cells that affects other target cells in the immune system.

cytokinesis (sy' toe kine ee' sis) [Gk. *kytos*: container + *kinein*: to move] The division of the cytoplasm of a dividing cell. (Contrast with mitosis.)

cytokinin (sy' toe kine' in) A member of a class of plant growth substances that plays roles in senescence, cell division, and other phenomena.

cytoplasm The contents of the cell, excluding the nucleus.

cytoplasmic determinants In animal development, gene products whose spatial distribution may determine such things as embryonic axes.

cytoplasmic segregation The asymmetrical distribution of cytoplasmic determinants in a developing animal embryo.

cytosine (C) (site' oh seen) A nitrogen-containing base found in DNA and RNA.

cytoskeleton The network of microtubules and microfilaments that gives a eukaryotic cell its shape and its capacity to arrange its organelles and to move.

cytosol The fluid portion of the cytoplasm, excluding organelles and other solids.

cytotoxic T cells (T_C) Cells of the cellular immune system that recognize and directly eliminate virus-infected cells. (Contrast with T-helper cells.)

D

DAG See diacylglycerol.

data Quantified observations about a system under study.

daughter chromosomes During mitosis, the separated chromatids from the beginning of anaphase onward.

dead space The lung volume that fails to be ventilated with fresh air (because the

lungs are never completely emptied during exhalation).

dead zones Regions in aquatic ecosystems that are devoid of aquatic life because eutrophication has resulted in severe oxygen depletion.

deciduous [L. *deciduus*: falling off] Pertaining to a woody plant that sheds its leaves but does not die.

declarative memory Memory of people, places, events, and things that can be consciously recalled and described. (Contrast with procedural memory.)

decomposer An organism that metabolizes organic compounds in debris and dead organisms, releasing inorganic material; found among the bacteria, protists, and fungi. See also detritivore, saprobe.

deductive logic Logical thought process that starts with a premise believed to be true then predicts what facts would also have to be true to be compatible with that premise. (Contrast with inductive logic.)

defensin A type of protein made by phagocytes that kills bacteria and enveloped viruses by insertion into their plasma membranes.

deficiency disease A condition (e.g., scurvy and beriberi) caused by chronic lack of any essential nutrient.

degeneracy The situation in which a single amino acid may be represented by any of two or more different codons in messenger RNA. Most of the amino acids can be represented by more than one codon.

deletion A mutation resulting from the loss of a continuous segment of a gene or chromosome. Such mutations almost never revert to wild type. (Contrast with duplication, point mutation.)

demethylase An enzyme that catalyzes the removal of the methyl group from cytosine, reversing DNA methylation.

demography The study of population structure and of the processes (**demographic events**, including births and deaths) by which it changes.

denaturation Loss of activity of an enzyme or nucleic acid molecule as a result of structural changes induced by heat or other means.

dendrites [Gk. *dendron*: tree] Branching fibers (processes) of a neuron. Dendrites are usually relatively short compared with the axon, and commonly carry information to the neuronal cell body.

denitrification Metabolic activity by which nitrate and nitrite ions are reduced to form nitrogen gas; carried out by certain soil bacteria.

denitrifiers Bacteria that release nitrogen to the atmosphere as nitrogen gas (N₂).

density See population density.

density-dependent Pertaining to an effect on population size that increases in proportion to population density.

density-independent Pertaining an effect on population size that acts independently of population density.

deoxyribonucleic acid See DNA.

deoxyribonucleoside triphosphates (dNTPs) The raw materials for DNA synthesis: deoxyadenosine triphosphate (dATP), deoxythymidine triphosphate (dTTP), deoxycytidine triphosphate (dCTP), and deoxyguanosine triphosphate (dGTP). Also called deoxyribonucleotides.

deoxyribose A five-carbon sugar found in nucleotides and DNA.

dependent variable In a scientific experiment, the response that is measured and analyzed as the independent variable is manipulated (See independent variable.)

depolarization A change in the resting potential across a membrane so that the inside of the cell becomes less negative, or even positive, compared with the outside of the cell. (Contrast with hyperpolarization.)

derived trait A trait that differs from the ancestral trait. (Contrast with synapomorphy.)

dermal tissue system The outer covering of a plant, consisting of epidermis in the young plant and periderm in a plant with extensive secondary growth. (Contrast with ground tissue system and vascular tissue system.)

descent with modification Darwin's premise that all species share a common ancestor and have diverged from one another gradually over time.

desmosome (dez' mo sowm) [Gk. *desmos*: bond + *soma*: body] An adhering junction between animal cells.

desmotubule A membrane extension connecting the endoplasmic reticulum of two plant cells that traverses the plasmodesma.

determinate growth A growth pattern in which the growth of an organism or organ ceases when an adult state is reached; characteristic of most animals and some plant organs. (Contrast with indeterminate growth.)

determination In development, the process whereby the fate of an embryonic cell or group of cells (e.g., to become epidermal cells or neurons) is set (becomes **determined**).

detritivore (di try' ti vore) [L. *detritus*: worn away + *vorare*: to devour] An organism that obtains its energy from the dead bodies or waste products (**detritus**) of other organisms.

development The process by which a multicellular organism, beginning with a single cell, goes through a series of changes, taking on the successive forms that characterize its life cycle.

developmental plasticity The capacity of an organism to alter its pattern of development in response to environmental conditions.

diacylglycerol (DAG) In hormone action, the second messenger produced by hydrolytic

removal of the head group of certain phospholipids.

diapause A period of developmental or reproductive arrest, entered in response to day length, that enables an organism to better survive.

diaphragm (dye' uh fram) [Gk. *diaphrassein*: barricade] (1) A sheet of muscle that separates the thoracic and abdominal cavities in mammals; responsible for breathing. (2) A method of birth control in which a sheet of rubber is fitted over the woman's cervix, blocking the entry of sperm.

diastole (dye ass' toll ee) [Gk. *dilation*] The portion of the cardiac cycle when the heart muscle relaxes. (Contrast with systole.)

dichotomous (dye cot' oh mus) [Gk. *dichot*: split in two; *tomia*: removed] A branching pattern in which the shoot divides at the apex producing two equivalent branches that subsequently never overlap.

diencephalon The portion of the vertebrate forebrain that develops into the thalamus and hypothalamus.

differential gene expression The hypothesis that, given that all cells contain all genes, what makes one cell type different from another is the difference in transcription and translation of those genes.

differentiation The process whereby originally similar cells follow different developmental pathways; the actual expression of determination.

diffuse coevolution The evolution of similar traits in suites of species experiencing similar selection pressures imposed by other suites of species with which they interact.

diffusion Random movement of molecules or other particles, resulting in even distribution of the particles when no barriers are present.

digestive vacuole In protists, an organelle specialized for digesting food ingested by endocytosis.

dihybrid cross A mating in which the parents differ with respect to the alleles of two loci of interest.

dikaryon (di care' ee ahn) [Gk. *di*: two + *karyon*: kernel] A cell or organism carrying two genetically distinguishable nuclei. Common in fungi.

dioecious (die eesh' us) [Gk. *di*: two + *oikos*: house] Pertaining to organisms in which the two sexes are "housed" in two different individuals, so that eggs and sperm are not produced in the same individuals. Examples: humans, fruit flies, date palms. (Contrast with monoecious.)

diploblastic Having two cell layers. (Contrast with triploblastic.)

diploid (dip' loid) [Gk. *diplos*: double] Having a chromosome complement consisting of two copies (homologs) of each chromosome. Designated $2n$. (Contrast with haploid.)

direct development Pattern of development (notably among insects) in

which hatchlings look like miniature versions of adults. (Contrast with metamorphosis.)

direct fitness That component of fitness resulting from an organism producing its own offspring. (Contrast with inclusive fitness, kin selection.)

directional selection Selection in which phenotypes at one extreme of the population distribution are favored. (Contrast with disruptive selection, stabilizing selection.)

directional succession Change in community composition after a disturbance (succession) that is characterized by an orderly progression culminating in a persistent state (the climax community). (Contrast with cyclical succession.)

disaccharide A carbohydrate made up of two monosaccharides (simple sugars).

discoidal cleavage In animal development, a type of incomplete cleavage that is common in fishes, reptiles, and birds, the eggs of which contain a dense yolk mass.

dispersal Movement of organisms away from a parent organism or from an existing population.

dispersion The distribution of individuals in space within a population. **Clumped dispersion** occurs when individuals tend to occupy the same space; **regular dispersion** is when the presence of one individual decreases the probability of another individual occupying the same space; and **random dispersion** assumes there is equal probability of any individual occupying any given space.

disruptive selection Selection in which phenotypes at both extremes of the population distribution are favored. (Contrast with directional selection; stabilizing selection.)

distal Away from the point of attachment or other reference point. (Contrast with proximal.)

distal convoluted tubule The portion of a renal tubule from where it reaches the renal cortex, just past the loop of Henle to where it joins a collecting duct. (Compare with proximal convoluted tubule.)

disturbance A short-term event that disrupts populations, communities, or ecosystems by changing the environment.

disulfide bridge The covalent bond between two sulfur atoms (—S—S—) linking two molecules or remote parts of the same molecule.

DNA (deoxyribonucleic acid) The fundamental hereditary material of all living organisms. In eukaryotes, stored primarily in the cell nucleus. A nucleic acid using deoxyribose rather than ribose.

DNA fingerprint An individual's unique pattern of allele sequences, commonly short tandem repeats and single nucleotide polymorphisms.

DNA helicase An enzyme that unwinds the double helix.

DNA ligase Enzyme that unites broken DNA strands during replication and recombination.

DNA methylation The addition of methyl groups to bases in DNA, usually cytosine or guanine.

DNA methyltransferase An enzyme that catalyzes the methylation of DNA.

DNA microarray A small glass or plastic square onto which thousands of single-stranded DNA sequences are fixed so that hybridization of cell-derived RNA or DNA to the target sequences can be performed.

DNA polymerase Any of a group of enzymes that catalyze the formation of DNA strands from a DNA template.

DNA replication The creation of a new strand of DNA in which DNA polymerase catalyzes the exact reproduction of an existing (template) strand of DNA.

DNA transposons Mobile genetic elements that move without making an RNA intermediate. (Contrast with retrotransposons.)

domain (1) An independent structural element within a protein. Encoded by recognizable nucleotide sequences, a domain often folds separately from the rest of the protein. Similar domains can appear in a variety of different proteins across phylogenetic groups (e.g., “homeobox domain”; “calcium-binding domain”). (2) In phylogenetics, the three monophyletic branches of life (Bacteria, Archaea, and Eukarya).

dominance In genetics, the ability of one allelic form of a gene to determine the phenotype of a heterozygous individual in which the homologous chromosomes carry both it and a different (recessive) allele. (Contrast with recessive.)

dormancy A condition in which normal activity is suspended, as in some spores, seeds, and buds.

dorsal [L. *dorsum*: back] Toward or pertaining to the back or upper surface. (Contrast with ventral.)

dorsal lip In amphibian embryos, the dorsal segment of the blastopore. Also called the “organizer,” this region directs the development of nearby embryonic regions.

double fertilization In angiosperms, a process in which the nuclei of two sperm fertilize one egg. One sperm’s nucleus combines with the egg nucleus to produce a zygote, while the other combines with the same egg’s two polar nuclei to produce the first cell of the triploid endosperm (the tissue that will nourish the growing plant embryo).

double helix Refers to DNA and the (usually right-handed) coil configuration of two complementary, antiparallel strands.

downregulation A negative feedback process in which continuous high concentrations of a hormone can decrease the number of its receptors. (Contrast with upregulation.)

duodenum (do’ uh dee’ num) The beginning portion of the vertebrate small intestine. (Contrast with ileum, jejunum.)

duplication A mutation in which a segment of a chromosome is duplicated, often by the attachment of a segment lost from its homolog. (Contrast with deletion.)

E

ecdysone (eck die’ sone) [Gk. *ek*: out of + *dyo*: to clothe] In insects, a hormone that induces molting.

ecological economics Interdisciplinary field that works to assess the economic value of biodiversity.

ecological efficiency The overall transfer of energy from one trophic level to the next, expressed as the ratio of consumer production to producer production.

ecological survivorship curve See survivorship curves

ecological system One or more organisms plus the external environment with which they interact.

ecology [Gk. *oikos*: house] The scientific study of the interaction of organisms with their living (biotic) and nonliving (abiotic) environments.

ecosystem (eek’ oh sis tum) The organisms of a particular habitat, such as a pond or forest, together with the physical environment in which they live.

ecosystem engineer An organism that builds structures that alter existing habitats or create new habitats.

ecosystem services Processes by which ecosystems maintain resources that benefit human society.

ecotourism Ecologically responsible travel to natural places.

ectoderm [Gk. *ektos*: outside + *derma*: skin] The outermost of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skin, sense organs, and nervous system.

ectotherm [Gk. *ektos*: outside + *thermos*: heat] An animal that is dependent on external heat sources for regulating its body temperature (Contrast with endotherm.)

edema (i dee’ mah) [Gk. *oidema*: swelling] Tissue swelling caused by the accumulation of fluid.

edge effects Changes in ecological processes in a community caused by physical and biological factors originating in an adjacent community.

effector A component of a physiological system that responds to information by *effecting* changes (making change happen) in the internal environment; examples include muscles and the secretory cells of the digestive tract.

effector cells In cellular immunity, B cells and T cells that attack an antigen, either by secreting antibodies that bind to the antigen or by releasing molecules that destroy any cell bearing the antigen.

effector protein In cell signaling, a protein responsible for the cellular response to a signal transduction pathway.

efferent (ef’ ur unt) [L. *ex*: out + *ferre*: to bear] Carrying outward or away from, as in neurons that carry impulses outward from the central to the peripheral nervous system (**efferent neurons**), or a blood vessel that carries blood away from a structure. (Contrast with afferent.)

egg In all sexually reproducing organisms, the female gamete; in birds, reptiles, and some other vertebrates, a structure within which early embryonic development occurs. See also amniote egg, ovum.

electrical synapse A type of synapse at which action potentials spread directly from presynaptic cell to postsynaptic cell. (Contrast with chemical synapse.)

electrocardiogram (ECG or EKG) A graphic recording of electrical potentials from the heart.

electrochemical gradient The concentration gradient of an ion across a membrane plus the voltage difference across that membrane.

electroencephalogram (EEG) A graphic recording of electrical potentials from the brain.

electromagnetic radiation A self-propagating wave that travels through space and has both electrical and magnetic properties.

electron A subatomic particle outside the nucleus carrying a negative charge and very little mass.

electron shell The region surrounding the atomic nucleus at a fixed energy level in which electrons orbit.

electron transport The passage of electrons through a series of proteins with a release of energy which may be captured in a concentration gradient or in chemical form such as NADH or ATP.

electronegativity The tendency of an atom to attract electrons when it occurs as part of a compound.

electrophoresis See gel electrophoresis.

element A substance that cannot be converted to a simpler substance by ordinary chemical means.

elongation (1) In molecular biology, the addition of monomers to make a longer RNA or protein during transcription or translation. (2) Growth of a plant axis or cell primarily in the longitudinal direction.

embolus (em’ buh lus) [Gk. *embolos*: stopper] A circulating blood clot. Blockage of a blood vessel by an embolus or a bubble of gas is called an **embolism**. (Contrast with thrombus.)

embryo [Gk. *en*: within + *bryein*: to grow] A young animal, or young plant sporophyte, while it is still contained within a protective structure such as a seed, egg, or uterus.

embryo sac In angiosperms, the female gametophyte. Found within the ovule, it

consists of eight or fewer cells, membrane bounded, but without cellulose walls between them.

embryonic stem cell (ESC) A pluripotent cell in the blastocyst.

emergent property A property of a complex system that is not exhibited by its individual component parts.

emigration The deliberate and usually oriented departure of an organism from the habitat in which it has been living.

endemic (en dem' ik) [Gk. *endemos*: native] Confined to a particular region, thus often having a comparatively restricted distribution.

endergonic A chemical reaction in which the products have higher free energy than the reactants, thereby requiring free energy input to occur. (Contrast with exergonic.)

endocrine cells Cells that secrete substances into the extracellular fluid. (See also endocrine gland.)

endocrine gland (en' doh krin) [Gk. *endo*: within + *krinein*: to separate] An aggregation of secretory cells that secretes hormones into the blood. The endocrine system consists of all endocrine cells and endocrine glands in the body that produce and release hormones. (Contrast with exocrine gland.)

endocytosis A process by which liquids or solid particles are taken up by a cell through invagination of the plasma membrane. (Contrast with exocytosis.)

endoderm [Gk. *endo*: within + *derma*: skin] The innermost of the three embryonic germ layers delineated during gastrulation. Gives rise to the digestive and respiratory tracts and structures associated with them.

endodermis In plants, a specialized cell layer marking the inside of the cortex in roots and some stems. Frequently a barrier to free diffusion of solutes.

endomembrane system A system of intracellular membranes that exchange material with one another, consisting of the Golgi apparatus, endoplasmic reticulum, and lysosomes when present.

endometrium The epithelial lining of the uterus.

endoplasmic reticulum (ER) [Gk. *endo*: within + L. *reticulum*: net] A system of membranous tubes and flattened sacs found in the cytoplasm of eukaryotes. Exists in two forms: rough ER, studded with ribosomes; and smooth ER, lacking ribosomes.

endorphins Molecules in the mammalian brain that act as neurotransmitters in pathways that control pain.

endoskeleton [Gk. *endo*: within + *skleros*: hard] An internal skeleton covered by other, soft body tissues. (Contrast with exoskeleton.)

endosperm [Gk. *endo*: within + *sperma*: seed] A specialized triploid seed tissue found only in angiosperms; contains stored nutrients for the developing embryo.

endospore [Gk. *endo*: within + *spora*: to sow] In some bacteria, a resting structure that can survive harsh environmental conditions.

endosymbiosis theory [Gk. *endo*: within + *sym*: together + *bios*: life] The theory that the eukaryotic cell evolved via the engulfing of one prokaryotic cell by another.

endothelium The single layer of epithelial cells lining the interior of a blood vessel.

endotherm [Gk. *endo*: within + *thermos*: heat] An animal that can control its body temperature by the expenditure of its own metabolic energy. (Contrast with ectotherm.)

endotoxin A lipopolysaccharide that forms part of the outer membrane of certain Gram-negative bacteria that is released when the bacteria grow or lyse. (Contrast with exotoxin.)

energetic cost The difference between the energy an animal expends in performing a behavior and the energy it would have expended had it rested.

energy The capacity to do work or move matter against an opposing force. The capacity to accomplish change in physical and chemical systems.

energy budget A quantitative description of all paths of energy exchange between an animal and its environment.

enhancers Regulatory DNA sequences that bind transcription factors that either activate or increase the rate of transcription.

enkephalins Molecules in the mammalian brain that act as neurotransmitters in pathways that control pain.

enteric nervous system The nerve nets in the submucosa and between the smooth muscle layers of the vertebrate gut.

enthalpy (H) The total energy of a system.

entrain To advance or delay an organism's circadian clock each day so that it is in phase with the light-dark cycle of the organism's environment.

entropy (S) (en' tro pee) [Gk. *tropein*: to change] A measure of the degree of disorder in any system. Spontaneous reactions in a closed system are always accompanied by an increase in entropy.

enveloped virus A virus enclosed within a phospholipid membrane derived from its host cell.

environment Whatever surrounds and interacts with or otherwise affects a population, organism, or cell. May be external or internal.

environmental genomics Sequencing technique used when biologists are unable to work with the whole genome of a prokaryote species but instead examine individual genes collected from a random sample of the organism's environment.

environmental resistance Reduction in a population's growth rate caused by preemption of available resources by other individuals in the population.

environmentalism The use of ecological knowledge, along with economics, ethics, and many other considerations, to inform both personal decisions and public policy relating to stewardship of natural resources and ecosystems.

enzyme (en' zime) [Gk. *zyme*: to leaven (as in yeast bread)] A catalytic protein that speeds up a biochemical reaction.

enzyme-substrate complex (ES) An intermediate in an enzyme-catalyzed reaction; consists of the enzyme bound to its substrate(s).

epi- [Gk. upon, over] A prefix used to designate a structure located on top of another; for example, epidermis, epiphyte.

epiblast The upper or overlying portion of the avian blastula which is joined to the hypoblast at the margins of the blastodisc.

epiboly The movement of cells over the surface of the blastula toward the forming blastopore.

epidermis [Gk. *epi*: over + *derma*: skin] In plants and animals, the outermost cell layers. (Only one cell layer thick in plants.)

epididymis (epuh did' uh mus) [Gk. *epi*: over + *didymos*: testicle] Coiled tubules in the testes that store sperm and conduct sperm from the seminiferous tubules to the vas deferens.

epigenetics The scientific study of changes in the expression of a gene or set of genes that occur without change in the DNA sequence.

epinephrine (ep i nef' rin) [Gk. *epi*: over + *nephros*: kidney] The "fight or flight" hormone produced by the medulla of the adrenal gland; it also functions as a neurotransmitter. (Also known as adrenaline.)

epistasis Interaction between genes in which the presence of a particular allele of one gene determines whether another gene will be expressed.

epithelial tissue A type of animal tissue made up of sheets of cells that lines or covers organs, makes up tubules, and covers the surface of the body; one of the four major tissue types in multicellular animals.

epitope See antigenic determinant.

equilibrium Any state of balanced opposing forces and no net change.

equilibrium potential The membrane potential at which an ion is at electrochemical equilibrium, i.e., there is no net flux of the ion across the membrane.

ER See endoplasmic reticulum.

error signal In regulatory systems, any difference between the set point of the system and its current condition.

erythrocyte (ur rith' row site) [Gk. *erythros*: red + *kytos*: container] A red blood cell.

erythropoietin A hormone produced by the kidney in response to lack of oxygen that stimulates the production of red blood cells.

esophagus (i soff' i gus) [Gk. *oisophagos*: gullet] That part of the gut between the pharynx and the stomach.

essential amino acids Amino acids that an animal cannot synthesize for itself and must obtain from its food.

essential element A mineral nutrient required for normal growth and reproduction in plants and animals.

essential fatty acids Fatty acids that an animal cannot synthesize for itself and must obtain from its food.

ester linkage A condensation (water-releasing) reaction in which the carboxyl group of a fatty acid reacts with the hydroxyl group of an alcohol. Lipids, including most membrane lipids, are formed in this way. (Contrast with ether linkage.)

estivation (ess tuh vay' shun) [L. *aestivalis*: summer] A state of dormancy and hypometabolism that occurs during the summer; usually a means of surviving drought and/or intense heat. (Contrast with hibernation.)

estrogen Any of several steroid sex hormones; produced chiefly by the ovaries in mammals.

estrus (es' trus) [L. *oestrus*: frenzy] The period of heat, or maximum sexual receptivity, in some female mammals. Ordinarily, the estrus is also the time of release of eggs in the female.

estuary Aquatic biome in which salt water and fresh water mix, as when a river meets the ocean. Includes such ecosystems as salt marshes and mangrove forests.

ether linkage The linkage of two hydrocarbons by an oxygen atom (HC—O—CH). Ether linkages are characteristic of the membrane lipids of the Archaea. (Contrast with ester linkage.)

ethology [Gk. *ethos*: character + *logos*: study] An approach to the study of animal behavior that focuses on studying many species in natural environments and addresses questions about the evolution of behavior. (Compare with behaviorism.)

ethylene One of the plant growth hormones, the gas $H_2C=CH_2$. Involved in fruit ripening and other growth and developmental responses.

euchromatin Diffuse, uncondensed chromatin. Contains active genes that will be transcribed into mRNA. (Contrast with heterochromatin.)

eudicots Angiosperms with two embryonic cotyledons. (See also monocots.)

Eukarya One of the three domains of life; organisms made up of one or more eukaryotic cells. (See also eukaryotes.)

eukaryotes (yew car' ree oats) [Gk. *eu*: true + *karyon*: kernel or nucleus] Organisms whose cells contain their genetic material inside a nucleus. Includes all life other than the viruses, archaea, and bacteria. (Contrast with prokaryotes.)

eusocial Pertaining to a social group that includes nonreproductive individuals, as in honey bees.

eustachian tube A connection between the middle ear and the throat that allows air pressure to equilibrate between the middle ear and the outside world.

eutrophication (yoo trofe' ik ay' shun) [Gk. *eu*: truly + *trephein*: to flourish] The addition of nutrient materials to a body of water, resulting in changes in ecological processes and species composition therein.

evaporation The transition of water from the liquid to the gaseous phase.

evolution Any gradual change. Most often refers to organic or Darwinian evolution, which is the genetic and resulting phenotypic change in populations of organisms from generation to generation. (See macroevolution, microevolution; contrast with speciation.)

evolutionary developmental biology (evo-devo) The study of the interplay between evolutionary and developmental processes, with a focus on the genetic changes that give rise to novel morphology. Key concepts of evo-devo include modularity, genetic toolkits, genetic switches, and heterochrony.

evolutionary radiation The proliferation of many species within a single evolutionary lineage.

evolutionary reversal The reappearance of an ancestral trait in a group that had previously acquired a derived trait.

evolutionary theory The understanding and application of the mechanisms of evolutionary change to biological problems.

excision repair DNA repair mechanism that removes damaged DNA and replaces it with the appropriate nucleotide.

excitable Capable of generating an action potential.

excitatory Input from a neuron that causes depolarization of the recipient cell.

excited state The state of an atom or molecule when, after absorbing energy, it has more energy than in its normal, ground state.

excretion Release of metabolic wastes by an organism.

excretory systems In animals, organs that maintain the volume, solute concentration, and composition of the extracellular fluid by excreting water, solutes, and nitrogenous wastes in the form of urine.

exergonic A chemical reaction in which the products of the reaction have lower free energy than the reactants, resulting in a release of free energy. (Contrast with endergonic.)

exocrine gland (eks' oh krin) [Gk. *exo*: outside + *krinein*: to separate] Any gland, such as a salivary gland, that secretes to the outside of the body or into the gut. (Contrast with endocrine gland.)

exocytosis A process by which a vesicle within a cell fuses with the plasma membrane and releases its contents to the outside. (Contrast with endocytosis.)

exon A portion of a DNA molecule, in eukaryotes, that codes for part of a polypeptide. (Contrast with intron.)

exoskeleton (eks' oh skel' e ton) [Gk. *exos*: outside + *skleros*: hard] A hard covering on the outside of the body to which muscles are attached. (Contrast with endoskeleton.)

exotoxin A highly toxic, usually soluble protein released by living, multiplying bacteria. (Contrast with endotoxin.)

expanding triplet repeat A three-base-pair sequence in a human gene that is unstable and can be repeated a few to hundreds of times. Often, the more the repeats, the less the activity of the gene involved. Expanding triplet repeats occur in some human diseases such as Huntington's disease and fragile-X syndrome.

experiment A testing process to support or disprove hypotheses and to answer questions. The basis of the scientific method. See comparative experiment, controlled experiment.

expiratory reserve volume The amount of air that can be forcefully exhaled beyond the normal tidal expiration. (Contrast with inspiratory reserve volume, tidal volume, vital capacity.)

exploitation competition Competition in which individuals reduce the quantities of their shared resources. (Contrast with interference competition.)

exponential growth Growth, especially in the number of organisms in a population, which is a geometric function of the size of the growing entity: the larger the entity, the faster it grows. (Contrast with logistic growth.)

expression vector A DNA vector, such as a plasmid, that carries a DNA sequence for the expression of an inserted gene into mRNA and protein in a host cell.

expressivity The degree to which a genotype is expressed in the phenotype; may be affected by the environment.

extensor A muscle that extends an appendage. (Contrast with flexor.)

external fertilization The release of gametes into the environment; typical of aquatic animals. Also called spawning. (Contrast with internal fertilization.)

external gills Highly branched and folded extensions of the body surface that provide a large surface area for gas exchange with water; typical of larval amphibians and many larval insects.

extinction The termination of a lineage of organisms.

extracellular matrix A material of heterogeneous composition surrounding cells and performing many functions including adhesion of cells.

extraembryonic membranes Four membranes that support but are not part of the developing embryos of reptiles, birds, and mammals, defining these groups

phylogenetically as amniotes. (See amnion, allantois, chorion, yolk sac.)

extreme halophiles A group of euryarchaeotes that live exclusively in very salty environments.

extremophiles Archaea and bacteria that live and thrive under conditions (e.g., extremely high temperatures) that would kill most organisms.

eye cups Photosensory organs in flatworms; components of one of the simplest visual systems in animals.

F

5' end (5 prime) The end of a DNA or RNA strand that has a free phosphate group at the 5' carbon of the sugar (deoxyribose or ribose).

F₁ The first filial generation; the immediate progeny of a parental (P) mating.

F₂ The second filial generation; the immediate progeny of a mating between members of the F₁ generation.

facilitated diffusion Passive movement through a membrane involving a specific carrier protein; does not proceed against a concentration gradient. (Contrast with active transport, diffusion.)

facilitation In succession, modification of the environment by a colonizing species in a way that allows colonization by other species. (Contrast with inhibition.)

facultative anaerobe A prokaryote that can shift its metabolism between anaerobic and aerobic modes depending on the presence or absence of O₂. (Alternatively, facultative aerobe.)

fast-twitch fibers Skeletal muscle fibers that can generate high tension rapidly, but fatigue rapidly ("sprinter" fibers). Characterized by an abundance of enzymes of glycolysis. (Compare to slow-twitch fibers.)

fat (1) A triglyceride that is solid at room temperature. (Contrast with oil.) (2) Adipose tissue, one type of connective tissue. (See brown fat, white fat.)

fate map A diagram of the blastula showing which cells (blastomeres) are "fated" to contribute to specific tissues and organs in the mature body.

fatty acid A molecule made up of a long nonpolar hydrocarbon chain and a polar carboxyl group. Found in many lipids.

fauna (faw' nah) All the animals found in a given area. (Contrast with flora.)

FD (FLOWERING LOCUS D) Gene coding for a transcription factor in the shoot apical meristem that binds to florigen; involved in the induction of flowering.

feces [L. *faeces*: dregs] Waste excreted from the digestive system.

fecundity The average number of offspring produced by each female.

feedback In regulatory systems, information about the relationship between the set point of the system and its

current state (Contrast with feedforward information).

feedback inhibition A mechanism for regulating a metabolic pathway in which the end product of the pathway can bind to and inhibit the enzyme that catalyzes the first committed step in the pathway. Also called end-product inhibition.

feedforward information In regulatory systems, information that changes the set point of the system. (Contrast with feedback.)

fermentation (fur men tay' shun) [L. *fermentum*: yeast] The anaerobic degradation of a substance such as glucose to smaller molecules such as lactic acid or alcohol with the extraction of energy.

fertilization Union of gametes. Also known as syngamy.

fertilizer Any of a number of substances added to soil to improve the soil's capacity to support plant growth. May be organic or inorganic.

fetus Medical and legal term for the stages of a developing human embryo from about the eighth week of pregnancy (the point at which all major organ systems have formed) to the moment of birth.

fiber In angiosperms, an elongated, tapering sclerenchyma cell, usually with a thick cell wall, that serves as a support function in xylem. (See also muscle fiber.)

fibrin A protein that polymerizes to form long threads that provide structure to a blood clot.

fibrinogen A circulating protein that can be stimulated to fall out of solution and provide the structure for a blood clot.

fibrous root system A root system typical of monocots composed of numerous thin adventitious roots that are all roughly equal in diameter. (Contrast with taproot system.)

Fick's law of diffusion An equation that describes the factors that determine the rate of diffusion of a molecule from an area of higher concentration to an area of lower concentration.

fight-or-flight response A rapid physiological response to a sudden threat mediated by the hormone epinephrine.

filament In flowers, the part of a stamen that supports the anther.

filter feeder An organism that feeds on organisms much smaller than itself that are suspended in water or air by means of a straining device.

first filial generation See F₁.

first law of thermodynamics The principle that energy can be neither created nor destroyed.

fission See binary fission.

fitness The contribution of a genotype or phenotype to the genetic composition of subsequent generations, relative to the contribution of other genotypes or phenotypes. (See also inclusive fitness.)

fixed action pattern In ethology, a genetically determined behavior that is performed without learning, stereotypic (performed the same way each time), and not modifiable by learning.

flagellum (fla jell' um) (plural: flagella) [L. *flagellum*: whip] Long, whiplike appendage that propels cells. Prokaryotic flagella differ sharply from those found in eukaryotes.

flexor A muscle that flexes an appendage. (Contrast with extensor.)

flora (flore' ah) All of the plants found in a given area. (Contrast with fauna.)

floral meristem In angiosperms, a meristem that forms the floral organs (sepals, petals, stamens, and carpels).

floral organ identity genes In angiosperms, genes that determine the fates of floral meristem cells; their expression is triggered by the products of meristem identity genes.

florigen A plant hormone involved in the conversion of a vegetative shoot apex to a flower.

flower The sexual structure of an angiosperm.

fluid feeder An animal that feeds on fluids it extracts from the bodies of other organisms; examples include nectar-feeding birds and blood-sucking insects.

fluid mosaic model A molecular model for the structure of biological membranes consisting of a fluid phospholipid bilayer in which suspended proteins are free to move in the plane of the bilayer.

flux [L.: flow] In ecology, the flow of an element into or out of a compartment of the biosphere.

follicle [L. *folliculus*: little bag] In female mammals, an immature egg surrounded by nutritive cells.

follicle-stimulating hormone (FSH) A gonadotropin produced by the anterior pituitary.

food chain A portion of a food web, most commonly a simple sequence of prey species and the predators that consume them.

food web The complete set of food links between species in a community; a diagram indicating which ones are the eaters and which are eaten.

forebrain The region of the vertebrate brain that comprises the cerebrum, thalamus, and hypothalamus.

fossil Any recognizable structure originating from an organism, or any impression from such a structure, that has been preserved over geological time.

fossil fuels Fuels, including oil, natural gas, coal, and peat, formed over geologic time from organic material buried in anaerobic sediments.

founder effect Random changes in allele frequencies resulting from establishment of a population by a very small number of individuals.

fovea [L. *fovea*: a small pit] In the vertebrate retina, the area of most distinct vision.

frame-shift mutation The addition or deletion of a single or two adjacent nucleotides in a gene's sequence. Results in the misreading of mRNA during translation and the production of a nonfunctional protein. (Contrast with missense mutation, nonsense mutation, silent mutation.)

Frank-Starling law The stroke volume of the heart increases with increased return of blood to the heart.

free energy (G) Energy that is available for doing useful work, after allowance has been made for the increase or decrease of disorder.

frequency-dependent selection Selection that changes in intensity with the proportion of individuals in a population having the trait.

frontal lobe The largest of the brain lobes in humans; involved with feeling and planning functions; includes the primary motor cortex.

frugivore [L. *frugis*; fruit + *vorare*: to devour] An animal that eats fruit.

fruit In angiosperms, a ripened and mature ovary (or group of ovaries) containing the seeds. Sometimes applied to reproductive structures of other groups of plants.

FT (FLOWERING LOCUS T) Gene that codes for florigen, a small, diffusible protein involved in the induction of flowering.

fugitive species A species that leave an otherwise suitable habitat in order to avoid competition with another species.

full census A count of every individual in a population. Can only be achieved if individuals are large and distinct enough to be identifiable by the census taker; population sizes are more usually estimated using sampling methods.

functional genomics The assignment of functional roles to the proteins encoded by genes identified by sequencing entire genomes.

functional group A characteristic combination of atoms that contributes specific properties (such as charge or polarity) when attached to larger molecules (e.g., carboxyl group; amino group).

fundamental niche A species' niche as defined by its physiological capabilities. (Contrast with realized niche.)

G

G protein A membrane protein involved in signal transduction; characterized by binding GDP or GTP.

G protein-linked receptors A class of receptors that change configuration upon ligand binding such that a G protein binding site is exposed on the cytoplasmic domain of the receptor, initiating a signal transduction pathway.

G1 In the cell cycle, the gap between the end of mitosis and the onset of the S phase.

G1-to-S transition In the cell cycle, the point at which G1 ends and the S phase begins.

G2 In the cell cycle, the gap between the S (synthesis) phase and the onset of mitosis.

gain of function mutation A mutation that results in a protein with a new function. (Contrast with loss of function mutation.)

gallbladder In the human digestive system, an organ in which bile is stored.

gametangium (gam uh tan' gee um) (plural: gametangia) [Gk. *gamos*: marriage + *angeion*: vessel] Any plant or fungal structure within which a gamete is formed.

gamete (gam' eet) [Gk. *gamete* / *gametes*: wife, husband] The mature sexual reproductive cell: the egg or the sperm.

gametogenesis (ga meet' oh jen' e sis) The specialized series of cellular divisions that leads to the production of gametes. (See also oogenesis, spermatogenesis.)

gametophyte (ga meet' oh fyte) In plants and photosynthetic protists with alternation of generations, the multicellular haploid phase that produces the gametes. (Contrast with sporophyte.)

ganglion (gang' glee un) (plural: ganglia) [Gk. *lump*] A cluster of neurons that have similar characteristics or function.

ganglion cells Cells at the front of the human retina that transmit information from the bipolar cells to the brain.

gap genes In *Drosophila* development, segmentation genes that define broad areas along the anterior-posterior axis of the early embryo. Part of a developmental cascade that includes maternal effect genes, pair rule genes, segment polarity genes, and Hox genes.

gap junction A 2.7-nanometer gap between plasma membranes of two animal cells, spanned by protein channels. Gap junctions allow chemical substances or electrical signals to pass from cell to cell.

gastric pits Deep infoldings in the walls of the stomach lined with secretory cells.

gastrin A hormone secreted by cells in the lower region of the stomach that stimulates the secretion of digestive juices as well as movements of the stomach.

gastrovascular cavity Serving for both digestion (gastro) and circulation (vascular); in particular, the central cavity of the body of jellyfish and other cnidarians.

gastrulation Development of a blastula into a gastrula. In embryonic development, the process by which a blastula is transformed by massive movements of cells into a *gastrula*, an embryo with three germ layers and distinct body axes.

gated channel A membrane protein that changes its three-dimensional shape, and therefore its ion conductance, in response to a stimulus. When open, it allows specific ions to move across the membrane.

gel electrophoresis (e lek' tro fo ree' sis) [L. *electrum*: amber + Gk. *phorain*: to bear] A

technique for separating molecules (such as DNA fragments) from one another on the basis of their electric charges and molecular weights by applying an electric field to a gel.

gene [Gk. *genes*: to produce] A unit of heredity. Used here as the unit of genetic function which carries the information for a polypeptide or RNA.

gene duplication The generation of extra copies of a gene in a genome over evolutionary time. A mechanism by which genomes can acquire new functions.

gene expression The transcription and translation into a protein of the information (nucleotide sequence) contained in a gene.

gene family A set of similar genes derived from a single parent gene; need not be on the same chromosomes. The vertebrate globin genes constitute a classic example of a gene family.

gene flow Exchange of genes between populations through migration of individuals or movements of gametes.

gene pool All of the different alleles of all of the genes existing in all individuals of a population.

gene therapy Treatment of a genetic disease by providing patients with cells containing functioning alleles of the genes that are nonfunctional in their bodies.

gene tree A graphic representation of the evolutionary relationships of a single gene in different species or of the members of a gene family.

gene-for-gene concept In plants, a mechanism of resistance to pathogens in which resistance is triggered by the specific interaction of the products of a pathogen's *Avr* genes and a plant's *R* genes.

general transcription factors In eukaryotes, transcription factors that bind to the promoters of most protein-coding genes and are required for their expression. Distinct from transcription factors that have specific regulatory effects only at certain promoters or classes of promoters.

genetic code The set of instructions, in the form of nucleotide triplets, that translate a linear sequence of nucleotides in mRNA into a linear sequence of amino acids in a protein.

genetic drift Changes in gene frequencies from generation to generation as a result of random (chance) processes.

genetic linkage Association between genes on the same chromosome such that they do not show random assortment and seldom recombine; the closer the genes, the lower the frequency of recombination.

genetic map The positions of genes along a chromosome as revealed by recombination frequencies.

genetic marker (1) In gene cloning, a gene of identifiable phenotype that indicates the presence of another gene, DNA segment, or chromosome fragment. (2) In general, a DNA sequence such as a single nucleotide polymorphism whose presence is correlated

with the presence of other linked genes on that chromosome.

genetic screen A technique for identifying genes involved in a biological process of interest. Involves creating a large collection of randomly mutated organisms and identifying those individuals that are likely to have a defect in the pathway of interest. The mutated gene(s) in those individuals can then be isolated for further study.

genetic structure The frequencies of different alleles at each locus and the frequencies of different genotypes in a Mendelian population.

genetic switches Mechanisms that control how the genetic toolkit is used, such as promoters and the transcription factors that bind them. The signal cascades that converge on and operate these switches determine when and where genes will be turned on and off.

genetic toolkit A set of developmental genes and proteins that is common to most animals and is hypothesized to be responsible for the evolution of their differing developmental pathways.

genetics The scientific study of the structure, functioning, and inheritance of genes, the units of hereditary information.

genome (jee' nome) The complete DNA sequence for a particular organism or individual.

genome sequencing Determination of the nucleotide base sequence of the entire genome of an organism.

genomic imprinting The form of a gene's expression is determined by parental source (i.e., whether the gene is inherited from the male or female parent).

genomic library All of the cloned DNA fragments generated by the breakdown of genomic DNA into smaller segments.

genomics The scientific study of entire sets of genes and their interactions.

genotype (jean' oh type) [Gk. *gen*: to produce + *typos*: impression] An exact description of the genetic constitution of an individual, either with respect to a single trait or with respect to a larger set of traits. (Contrast with phenotype.)

genotype frequency The proportion of a genotype among individuals in a population.

genus (jean' us) (plural: genera) [Gk. *genos*: stock, kind] A group of related, similar species recognized by taxonomists with a distinct name used in binomial nomenclature.

geographic range The region within which a species occurs.

germ cell [L. *germen*: to beget] A reproductive cell or gamete of a multicellular organism. (Contrast with somatic cell.)

germ layers The three embryonic layers formed during gastrulation (ectoderm, mesoderm, and endoderm). Also called cell layers or tissue layers.

germ line mutation Mutation in a cell that produces gametes (i.e., a germ line cell). (Contrast with somatic mutation.)

germination Sprouting of a seed or spore.

gestation (jes tay' shun) [L. *gestare*: to bear] The period during which the embryo of a mammal develops within the uterus. Also known as pregnancy.

ghrelin A hormone produced and secreted by cells in the stomach that stimulates appetite.

gibberellin (jib er el' lin) A class of plant growth hormones playing roles in stem elongation, seed germination, flowering of certain plants, etc.

gill An organ specialized for gas exchange with water.

gizzard (giz' erd) [L. *gigeria*: cooked chicken parts] The second of two stomachlike organs in birds, other reptiles, earthworms, and various insects, that grinds up food, sometimes with the aid of fragments of stone. (See also crop.)

glia (glee' uh) [Gk. *glia*: glue] One of the two classes of neural cells (along with neurons, with which glia interact); glia do not typically conduct action potentials. Types of glia include astrocytes, oligodendrocytes, and Schwann cells.

global nitrogen cycle The movement of nitrogen through the biosphere. Steps in the cycle include the fixation of nitrogen gas (N₂) to ammonia; nitrification of the fixed nitrogen to nitrate by bacteria; nitrate reduction by plants; and denitrification back to N₂ by bacteria.

glomerular filtration rate (GFR) The rate at which the blood is filtered in the glomeruli of the kidney.

glomerulus (glo mare' yew lus) [L. *glomus*: ball] Sites in the kidney where blood filtration takes place. Each glomerulus consists of a knot of capillaries served by afferent and efferent arterioles.

glucagon Hormone produced by alpha cells of the pancreatic islets of Langerhans. Glucagon stimulates the liver to break down glycogen and release glucose into the circulation.

gluconeogenesis The biochemical synthesis of glucose from other substances, such as amino acids, lactate, and glycerol.

glucose [Gk. *gleukos*: sugar, sweet wine] The most common monosaccharide; the monomer of the polysaccharides starch, glycogen, and cellulose.

glyceraldehyde 3-phosphate (G3P) A phosphorylated three-carbon sugar; an intermediate in glycolysis and photosynthetic carbon fixation.

glycerol (gliss' er ole) A three-carbon alcohol with three hydroxyl groups; a component of phospholipids and triglycerides.

glycogen (gly' ko jen) [Gk. *glyk*: sweet] An energy storage polysaccharide found in

animals and fungi; a branched-chain polymer of glucose, similar to starch.

glycolipid A lipid to which sugars are attached.

glycolysis (gly kol' li sis) [Gk. *gleukos*: sugar + *lysis*: break apart] The enzymatic breakdown of glucose to pyruvic acid.

glycoprotein A protein to which sugars are attached.

glycosidic linkage Bond between carbohydrate (sugar) molecules through an intervening oxygen atom (–O–).

glycosylation The addition of carbohydrates to another type of molecule, such as a protein.

glyoxysome (gly ox' ee soam) An organelle found in plants, in which stored lipids are converted to carbohydrates.

Golgi apparatus (goal' jee) A system of concentrically folded membranes found in the cytoplasm of eukaryotic cells; functions in secretion from the cell by exocytosis.

Golgi tendon organ A mechanoreceptor found in tendons and ligaments; provides information about the force generated by a contracting muscle.

gonad (go' nad) [Gk. *gone*: seed] An organ that produces gametes in animals: either an ovary (female gonad) or testis (male gonad).

gonadotropin A trophic hormone that stimulates the gonads.

gonadotropin-releasing hormone (GnRH) Hormone produced by the hypothalamus that stimulates the anterior pituitary to secrete gonadotropins.

Gondwana The large southern land mass that existed from the Cambrian (540 mya) to the Jurassic (138 mya). Present-day remnants are South America, Africa, India, Australia, and Antarctica.

graded membrane potential Small local change in membrane potential caused by opening or closing of ion channels.

grafting Artificial transplantation of tissue from one organism to another. In horticulture, the transfer of a bud or stem segment from one plant onto the root of another as a form of asexual reproduction.

gram stain A differential purple stain useful in characterizing bacteria. The peptidoglycan-rich cell walls of gram-positive bacteria stain purple; cell walls of gram-negative bacteria generally stain orange.

gravitropism [L. *gravitas*: weight, force; Gk. *tropos*: to turn] A directed plant growth response to gravity.

gray crescent In frog development, a band of diffusely pigmented cytoplasm on the side of the egg opposite the site of sperm entry. Arises as a result of cytoplasmic rearrangements that establish the anterior–posterior axis of the zygote.

gray matter In the nervous system, tissue that is rich in neuronal cell bodies. (Contrast with white matter.)

greenhouse gases Gases in the atmosphere, such as carbon dioxide and methane, that are transparent to sunlight, but trap heat radiating from Earth's surface, causing heat to build up at Earth's surface.

gross primary production The amount of energy captured by the primary producers in a community.

gross primary productivity (GPP) The rate at which the primary producers in a community turn solar energy into stored chemical energy via photosynthesis.

ground meristem That part of an apical meristem that gives rise to the ground tissue system of the primary plant body.

ground tissue system Those parts of the plant body not included in the dermal or vascular tissue systems. Ground tissues function in storage, photosynthesis, and support.

growth An increase in the size of the body and its organs by cell division and cell expansion.

growth factor A chemical signal that stimulates cells to divide.

growth hormone A peptide hormone released by the anterior pituitary that stimulates many anabolic processes.

guanine (G) (gwan' een) A nitrogen-containing base found in DNA, RNA, and GTP.

guard cells In plants, specialized, paired epidermal cells that surround and control the opening of a stoma (pore). *See* stoma.

gustation The sense of taste.

gut An animal's digestive tract.

gymnosperms Seed plants that do not produce flowers or fruits; one of the two major groups of living seed plants. (*See also* angiosperms.)

gyrus (ji' rus) [Gk. *gyros*: spiral] *See* convolutions.

H

habitat The particular environment in which an organism lives.

habitat patches Also called **habitat islands**; areas of suitable habitat for a species that are separated by substantial areas of unsuitable habitat.

Hadley cells Patterns of vertical atmospheric circulation that influence surface winds and precipitation patterns according to latitude.

hair cell A type of mechanoreceptor in animals. Detects sound waves and other forms of motion in air or water.

half-life The time required for half of a sample of a radioactive isotope to decay to its stable, nonradioactive form, or for a drug or other substance to reach half its initial dosage.

halophyte (hal' oh fyte) [Gk. *halos*: salt + *phyton*: plant] A plant that grows in a saline (salty) environment.

Hamilton's rule The principle that, for an apparent altruistic behavior to be adaptive, the fitness benefit of that act to the recipient times the degree of relatedness of the performer and the recipient must be greater than the cost to the performer.

haplodiploidy A sex determination mechanism in which diploid individuals (which develop from fertilized eggs) are female and haploid individuals (which develop from unfertilized eggs) are male; typical of hymenopterans.

haploid (hap' loid) [Gk. *haploides*: single] Having a chromosome complement consisting of just one copy of each chromosome; designated $1n$ or n . (Contrast with diploid.)

haplotype Linked nucleotide sequences that are usually inherited as a unit (as a "sentence" rather than as individual "words").

Hardy-Weinberg equilibrium In a sexually reproducing population, the allele frequency at a given locus that is not being acted on by agents of evolution; the conditions that would result in no evolution in a population.

haustorium (haw stor' ee um) (plural: haustoria) [L. *haustus*: draw up] A specialized hypha or other structure by which fungi and some parasitic plants draw nutrients from a host plant.

Haversian systems Units of organization in compact bone that reflect the action of intercommunicating osteoblasts.

heart In circulatory systems, a muscular pump that moves extracellular fluid around the body.

heat of vaporization The energy that must be supplied to convert a molecule from a liquid to a gas at its boiling point.

heat shock proteins Chaperone proteins expressed in cells exposed to high or low temperatures or other forms of environmental stress.

helical Shaped like a screw or spring (helix); this shape occurs in DNA and proteins.

helper T cells *See* T-helper cells.

hemiparasite A parasitic plant that can photosynthesize, but derives water and mineral nutrients from the living body of another plant. (Contrast with holoparasite.)

hemizygous (hem' ee zie' gus) [Gk. *hemi*: half + *zygotos*: joined] In a diploid organism, having only one allele for a given trait, typically the case for X-linked genes in male mammals and Z-linked genes in female birds. (Contrast with homozygous, heterozygous.)

hemoglobin (hee' mo glow bin) [Gk. *heama*: blood + L. *globus*: globe] Oxygen-transporting protein found in the red blood cells of vertebrates (and found in some invertebrates).

Hensen's node In avian embryos, a structure at the anterior end of the primitive groove; determines the fates of cells passing over it during gastrulation.

hepatic (heh pat' ik) [Gk. *hepar*: liver] Pertaining to the liver.

herbivore (ur' bi vore) [L. *herba*: plant + *vorare*: to devour] An animal that eats plant tissues. (Contrast with carnivore, detritivore, omnivore.)

heritable trait A trait that is at least partly determined by genes.

hermaphroditism (her maf' row dite ism) The coexistence of both female and male sex organs in the same organism.

hetero- [Gk.: *heteros*: other, different] A prefix indicating two or more different conditions, structures, or processes. (Contrast with homo-.)

heterochromatin Densely packed, dark-staining chromatin; any genes it contains are usually not transcribed.

heterochrony [Gk.: different time] Alteration in the timing of developmental events, contributing to the evolution different phenotypes in the adult.

heterocyst A large, thick-walled cell type in the filaments of certain cyanobacteria that performs nitrogen fixation.

heterometry [Gk.: different measure] Alteration in the level of gene expression, and thus in the amount of protein produced, during development, contributing to the evolution of different phenotypes in the adult.

heteromorphic (het' er oh more' fik) [Gk.: different form] Having a different form or appearance, as two heteromorphic life stages of a plant. (Contrast with isomorphic.)

heterosis The superior fitness of heterozygous offspring as compared with that of their dissimilar homozygous parents. Also called hybrid vigor.

heterosporous (het' er os' por us) Producing two types of spores, one of which gives rise to a female megaspore and the other to a male microspore. (Contrast with homosporous.)

heterotherm An animal that regulates its body temperature at a constant level at some times but not others, such as a hibernator.

heterotopy [Gk.: different place] Spatial differences in gene expression during development, controlled by developmental regulatory genes and contributing to the evolution of distinctive adult phenotypes.

heterotroph (het' er oh trof) [Gk. *heteros*: different + *trophe*: feed] An organism that requires preformed organic molecules as food. (Contrast with autotroph.)

heterotrophic succession Succession in detritus-based communities, which differs from other types of succession in taking place without the participation of plants.

heterotypy [Gk.: different kind] Alteration in a developmental regulatory gene itself rather than the expression of the genes it controls. (Contrast with heterochrony; heterometry; heterotopy.)

heterozygous (het' er oh zie' gus) [Gk. *heteros*: different + *zygotos*: joined] In diploid

organisms, having different alleles of a given gene on the pair of homologs carrying that gene. (Contrast with homozygous.)

heterozygous carrier An individual that carries a recessive allele for a phenotype of interest (e.g., a genetic disease); the individual does not show the phenotype, but may have progeny with the phenotype if the other parent also carries the recessive allele.

hexose [Gk. *hex*: six] A sugar containing six carbon atoms.

hibernation [L. *hibernum*: winter] The state of inactivity of some animals during winter; marked by a drop in body temperature and metabolic rate. (Contrast with estivation)

high-density lipoproteins (HDLs) Lipoproteins that remove cholesterol from tissues and carry it to the liver; HDLs are the “good” lipoproteins associated with good cardiovascular health.

high-throughput sequencing Rapid DNA sequencing on a micro scale in which many fragments of DNA are sequenced in parallel.

highly repetitive sequences Short (less than 100 bp), nontranscribed DNA sequences, repeated thousands of times in tandem arrangements.

hindbrain The region of the developing vertebrate brain that gives rise to the medulla, pons, and cerebellum.

hippocampus [Gk. sea horse] A part of the forebrain that takes part in long-term memory formation.

histamine (hiss’ tah meen) A substance released by damaged tissue, or by mast cells in response to allergens. Histamine increases vascular permeability, leading to edema (swelling). (Contrast with histone deacetylase.)

histone Any one of a group of proteins forming the core of a nucleosome, the structural unit of a eukaryotic chromosome.

histone acetyltransferases Enzymes involved in chromatin remodeling. Add acetyl groups to the tail regions of histone proteins.

histone deacetylase In chromatin remodeling, an enzyme that removes acetyl groups from the tails of histone proteins. (Contrast with histone acetyltransferases.)

HIV Human immunodeficiency virus, the retrovirus that causes acquired immune deficiency syndrome (AIDS).

holoparasite A fully parasitic plant (i.e., one that does not perform photosynthesis).

homeobox 180-base-pair segment of DNA found in certain homeotic genes. A specific sequence within the homeobox—the **homeodomain**—regulates the expression of other genes and through this regulation controls large-scale developmental processes. (See homeotic genes.)

homeostasis (home’ ee o sta’ sis) [Gk. *homos*: same + *stasis*: position] The maintenance of a steady state, such as a constant temperature, by means of

physiological or behavioral feedback responses.

homeotic genes Genes that act during development to determine the formation of an organ from a region of the embryo. (Compare with Hox genes.)

homeotic mutation Mutation in a homeotic gene that results in the formation of a different organ than that normally made by a region of the embryo.

homing In animal navigation, the ability to return to a nest site, burrow, or other specific location.

hominid Lineage that includes all modern and extinct Great Apes (i.e., humans, gorillas, chimpanzees, orangutans, and their ancestors.)

hominin Lineages that includes modern humans (*Homo sapiens*) and their extinct ancestors (e.g., Australopithecines; *Homo erectus*.)

homo- [Gk. *homos*: same] A prefix indicating two or more similar conditions, structures, or processes. (Contrast with hetero-.)

homolog (1) In cytogenetics, one of a pair (or larger set) of chromosomes having the same overall genetic composition and sequence. In diploid organisms, each chromosome inherited from one parent is matched by an identical (except for mutational changes) chromosome—its homolog—from the other parent. (2) In evolutionary biology, one of two or more features in different species that are similar by reason of descent from a common ancestor.

homologous pair A pair of matching chromosomes made up of a chromosome from each of the two sets of chromosomes in a diploid organism.

homologous recombination Exchange of segments between two DNA molecules based on sequence similarity between the two molecules. The similar sequences align and crossover. Used to create knockout mutants in mice and other organisms.

homology (ho mol’ o jee) [Gk. *homologia*: of one mind; agreement] A similarity between two or more features that is due to inheritance from a common ancestor. The structures are said to be *homologous*, and each is a *homolog* of the others.

homoplasy (home’ uh play zee) [Gk. *homos*: same + *plastikos*: shape, mold] The presence in multiple groups of a trait that is not inherited from the common ancestor of those groups. Can result from convergent evolution, evolutionary reversal, or parallel evolution.

homosporous Producing a single type of spore that gives rise to a single type of gametophyte, bearing both female and male reproductive organs. (Contrast with heterosporous.)

homotypic Pertaining to adhesion of cells of the same type. (Contrast with heterotypic.)

homozygous (home’ oh zie’ gus) [Gk. *homos*: same + *zygotos*: joined] In diploid organisms, having identical alleles of a given gene on both homologous chromosomes. An

individual may be a homozygote with respect to one gene and a heterozygote with respect to another. (Contrast with heterozygous.)

horizons The horizontal layers of a soil profile, including the topsoil (A horizon), subsoil (B horizon) and parent rock or bedrock (C horizon).

hormone (hore’ mone) [Gk. *hormon*: to excite, stimulate] A chemical signal produced in minute amounts at one site in a multicellular organism and transported to another site where it acts on target cells.

host An organism that harbors a parasite or symbiont and provides it with nourishment.

Hox genes Conserved homeotic genes found in vertebrates, *Drosophila*, and other animal groups. Hox genes contain the homeobox and specify pattern and axis formation in these animals.

human chorionic gonadotropin (hCG) A hormone secreted by the placenta which sustains the corpus luteum and helps maintain pregnancy.

Human Genome Project A publicly and privately funded research effort, successfully completed in 2003, to produce a complete DNA sequence for the entire human genome.

humoral immune response The response of the immune system mediated by B cells that produces circulating antibodies active against extracellular bacterial and viral infections. (Contrast with cellular immune response.)

humus (hew’ mus) The partly decomposed remains of plants and animals on the surface of a soil.

hybrid (high’ brid) [L. *hybrida*: mongrel] (1) The offspring of genetically dissimilar parents. (2) In molecular biology, a double helix formed of nucleic acids from different sources.

hybrid vigor See heterosis.

hybrid zone A region of overlap in the ranges of two closely related species where the species may hybridize.

hybridize (1) In genetics, to combine the genetic material of two distinct species or of two distinguishable populations within a species. (2) In molecular biology, to form a double-stranded nucleic acid in which the two strands originate from different sources.

hydrocarbon A compound containing only carbon and hydrogen atoms.

hydrogen bond A weak electrostatic bond which arises from the attraction between the slight positive charge on a hydrogen atom and a slight negative charge on a nearby oxygen or nitrogen atom.

hydrologic cycle The movement of water from the oceans to the atmosphere, to the soil, and back to the oceans.

hydrolysis reaction (high drol’ uh sis) [Gk. *hydro*: water + *lysis*: break apart] A chemical reaction that breaks a bond by inserting the components of water ($AB + H_2O \rightarrow AH + BOH$). (Contrast with condensation reaction.)

hydrophilic (high dro fill' ik) [Gk. *hydro*: water + *philia*: love] Having an affinity for water. (Contrast with hydrophobic.)

hydrophobic (high dro foe' bik) [Gk. *hydro*: water + *phobia*: fear] Having no affinity for water. Uncharged and nonpolar groups of atoms are hydrophobic. (Contrast with hydrophilic.)

hydroponic Pertaining to a method of growing plants with their roots suspended in nutrient solutions instead of soil.

hydrostatic pressure Pressure generated by compression of liquid in a confined space. Generated in plants, fungi, and some protists with cell walls by the osmotic uptake of water. Generated in animals with closed circulatory systems by the beating of a heart.

hydrostatic skeleton A fluid-filled body cavity that transfers forces from one part of the body to another when acted on by surrounding muscles.

hydroxyl group The —OH group found on alcohols and sugars.

hyper- [Gk. *hyper*: above, over] Prefix indicating above, higher, more. (Contrast with hypo-.)

hyperaccumulators Plant species that store large quantities of heavy metals such as arsenic, cadmium, nickel, aluminum, and zinc.

hyperpolarization A change in the resting potential across a membrane so that the inside of a cell becomes more negative compared with the outside of the cell. (Contrast with depolarization.)

hypersensitive response A defensive response of plants to microbial infection in which phytoalexins and pathogenesis-related proteins are produced and the infected tissue undergoes apoptosis to isolate the pathogen from the rest of the plant.

hypertonic Having a greater solute concentration. Said of one solution compared with another. (Contrast with hypotonic, isotonic.)

hypha (high' fuh) (plural: hyphae) [Gk. *hyphē*: web] In the fungi and oomycetes, any single filament.

hypo- [Gk. *hypo*: beneath, under] Prefix indicating underneath, below, less. (Contrast with hyper-.)

hypoblast The lower tissue portion of the avian blastula which is joined to the epiblast at the margins of the blastodisc.

hypothalamus The part of the brain lying below the thalamus; it coordinates water balance, reproduction, temperature regulation, and metabolism.

hypothermia Below-normal body temperature.

hypothesis A tentative answer to a question, from which testable predictions can be generated. (Contrast with theory.)

hypotonic Having a lesser solute concentration. Said of one solution in comparing it to another. (Contrast with hypertonic, isotonic.)

hypoxia A deficiency of oxygen.

I

ileum The final segment of the small intestine. (See also duodenum, jejunum.)

imbibition Water uptake by a seed; first step in germination.

immediate hypersensitivity A rapid, extensive overreaction of the immune system against an allergen, resulting in the release of large amounts of histamine. (Contrast with delayed hypersensitivity.)

immediate memory A form of memory for events happening in the present that is almost perfectly photographic, but lasts only seconds.

immunity [L. *immunis*: exempt from] In animals, the ability to avoid disease when invaded by a pathogen by deploying various defense mechanisms.

immunoassay The use of antibodies to measure the concentration of an antigen in a sample.

immunoglobulins A class of proteins containing a tetramer consisting of four polypeptide chains—two identical light chains and two identical heavy chains—held together by disulfide bonds; active as receptors and effectors in the immune system.

immunological memory The capacity to more rapidly and massively respond to a second exposure to an antigen than occurred on first exposure.

imperfect flower A flower lacking either functional stamens or functional carpels. (Contrast with perfect flower.)

implantation The process by which the early mammalian embryo becomes attached to and embedded in the lining of the uterus.

imprinting In animal behavior, a rapid form of learning in which an animal learns, during a brief critical period, to make a particular response (which is then maintained for life) to some object or other organism. See also genomic imprinting.

in vitro [L.: in glass] A biological process occurring outside of the organism, in the laboratory. (Contrast with in vivo.)

in vitro evolution A method based on natural molecular evolution that uses artificial selection in the laboratory to rapidly produce molecules with novel enzymatic and binding functions.

in vivo [L.: in life] A biological process occurring within a living organism or cell. (Contrast with in vitro.)

inclusive fitness The sum of an individual's genetic contribution to subsequent generations both via production of its own offspring and via its influence on the survival of relatives who are not direct descendants. (Contrast with direct fitness)

incomplete cleavage A pattern of cleavage that occurs in many eggs that have a lot of yolk, in which the cleavage furrows do not penetrate all of it. (See also discoidal cleavage,

superficial cleavage; contrast with complete cleavage.)

incomplete dominance Condition in which the heterozygous phenotype is intermediate between the two homozygous phenotypes.

incomplete metamorphosis Insect development in which changes between instars are gradual. (Contrast with direct development; complete metamorphosis.)

independent assortment During meiosis, the random separation of genes carried on nonhomologous chromosomes into gametes so that inheritance of these genes is random. This principle was articulated by Mendel as his second law.

independent variable In a scientific experiment, a critical factor that is manipulated while all other factors are held constant. (Contrast with dependent variable.)

indeterminate growth A open-ended growth pattern in which an organism or organ continues to grow as long as it lives; characteristic of some animals and of plant shoots and roots. (Contrast with determinate growth.)

individual fitness See direct fitness.

induced fit A change in the shape of an enzyme caused by binding to its substrate that exposes the active site of the enzyme.

induced mutation A mutation resulting from exposure to a mutagen from outside the cell. (Contrast with spontaneous mutation.)

induced pluripotent stem cells (iPS cells) Multipotent or pluripotent animal stem cells produced from differentiated cells in vitro by the addition of several genes that are expressed.

induced responses Defensive responses that a plant produces only in the presence of a pathogen, in contrast to constitutive defenses, which are always present.

inducer (1) A compound that stimulates the synthesis of a protein. (2) In embryonic development, a substance that causes a group of target cells to differentiate in a particular way.

inducible genes Genes that are expressed only when their products—**inducible proteins**—are needed. (Contrast with constitutive genes.)

inducible Produced only in the presence of a particular compound or under particular circumstances. (Contrast with constitutive.)

induction In embryonic development, the process by which a factor produced and secreted by certain cells determines the fates of other cells.

inductive logic Involves making observations and then formulating one or more possible scenarios—hypotheses—that might explain those observations. (Contrast with deductive logic.)

inflammation A nonspecific defense against pathogens; characterized by redness, swelling, pain, and increased temperature.

inflorescence A structure composed of several to many flowers.

inflorescence meristem A meristem that produces floral meristems as well as other small leafy structures (bracts).

ingroup In a phylogenetic study, the group of organisms of primary interest. (Contrast with outgroup.)

inhibitor A substance that blocks a biological process.

inhibitory Input from a neuron that causes hyperpolarization of the recipient cell.

initials Cells that perpetuate plant meristems, comparable to animal stem cells. When an initial divides, one daughter cell develops into another initial, while the other differentiates into a more specialized cell.

initiation complex In protein translation, a combination of a small ribosomal subunit, an mRNA molecule, and the tRNA charged with the first amino acid coded for by the mRNA; formed at the onset of translation.

initiation site The place within a promoter where transcription begins.

innate defenses In animals, one of two general types of defenses against pathogens. Nonspecific and present in most animals. (Contrast with adaptive immunity.)

inner cell mass Derived from the mammalian blastula (blastocyst), the inner cell mass that will give rise to the yolk sac (via hypoblast) and embryo (via epiblast).

inorganic fertilizer A chemical or combination of chemicals applied to soil or plants to make up for a plant nutrient deficiency. Often contains the macronutrients nitrogen, phosphorus, and potassium (N-P-K).

inositol trisphosphate (IP₃) An intracellular second messenger derived from membrane phospholipids.

inspiratory reserve volume The amount of air that can be inhaled above the normal tidal inspiration. (Contrast with expiratory reserve volume, tidal volume, vital capacity.)

instar (in' star) An immature stage of an insect between molts.

insula (in' su lah) [L. *insula*: island] An area deep within the forebrain that appears to integrate physiological information from all over the body "feels" and may be involved in human consciousness. Also called the insular cortex.

insulin (in' su lin) [L. *insula*: island] A hormone synthesized in islet cells of the pancreas that promotes the conversion of glucose into the storage material, glycogen.

integral membrane proteins Proteins that are at least partially embedded in the plasma membrane. (Contrast with peripheral membrane proteins.)

integrin In animals, a transmembrane protein that mediates the attachment of epithelial cells to the extracellular matrix.

integument [L. *integumentum*: covering] A protective surface structure. In gymnosperms

and angiosperms, a layer of tissue around the ovule which will become the seed coat.

intercostal muscles Muscles between the ribs that can augment breathing movements by elevating and suppressing the rib cage.

interference competition Competition in which individuals actively interfere with one another's access to resources. (Contrast with exploitation competition.)

interference RNA (RNAi) See RNA interference.

interferons Glycoproteins produced by virus-infected animal cells; interferons increase the resistance of neighboring cells to the virus.

internal environment In multicellular organisms, includes blood plasma and interstitial fluid, i.e., the extracellular fluids that surround the cells.

internal fertilization The release of sperm into the female reproductive tract; typical of most terrestrial animals. (Contrast with external fertilization.)

internal gills Gills enclosed in protective body cavities; typical of mollusks, arthropods, and fishes. **interneuron** A neuron that communicates information between two other neurons.

interneuron A neuron that communicates information between two other neurons.

internode The region between two nodes of a plant stem.

interphase In the cell cycle, the period between successive nuclear divisions during which the chromosomes are diffuse and the nuclear envelope is intact. During interphase the cell is most active in transcribing and translating genetic information.

interspecific competition Competition between members of two or more species. (Contrast with intraspecific competition; see also exploitation competition, interference competition.)

interstitial fluid Extracellular fluid that is not contained in the vessels of a circulatory system.

intertidal zone A nearshore region of oceans that is periodically exposed to the air as the tides rise and fall.

intestine The portion of the gut following the stomach, in which most digestion and absorption occurs.

intraspecific competition Competition among members of the same species. (Contrast with interspecific competition.)

intrinsic rate of increase The rate at which a population is capable of growing when its density is low and environmental conditions are highly favorable.

intron Portion of a gene within the coding region that is transcribed into pre-mRNA but is spliced out prior to translation. (Contrast with exon.)

invasive species An exotic species that reproduces rapidly, spreads widely, and has

negative effects on the native species of the region to which it has been introduced.

invasiveness The ability of a pathogen to multiply in a host's body. (Contrast with toxigenicity.)

inversion A rare 180° reversal of the order of genes within a segment of a chromosome.

involution Cell movements that occur during gastrulation of frog embryos, giving rise to the archenteron.

ion (eye' on) [Gk. *ion*: wanderer] An electrically charged particle that forms when an atom gains or loses one or more electrons.

ion channel An integral membrane protein that allows ions to diffuse across the membrane in which it is embedded.

ion exchange In plants, a process by which protons produced by the plant's root displace mineral cations from clay particles in the surrounding soil.

ionic attraction An electrostatic attraction between positively and negatively charged ions.

ionotropic receptors A receptor that directly alters membrane permeability to a type of ion when it combines with its ligand.

iris (eye' ris) [Gk. *iris*: rainbow] The round, pigmented membrane that surrounds the pupil of the eye and adjusts its aperture to regulate the amount of light entering the eye.

island biogeography A theory proposing that the number of species on an island (or in another geographically defined and isolated area) represents a balance, or equilibrium, between the rate at which species immigrate to the island and the rate at which resident species go extinct.

islets of Langerhans Clusters of hormone-producing cells in the pancreas.

iso- [Gk. *iso*: equal] Prefix used for two separate entities that share some element of identity.

isomers Molecules consisting of the same numbers and kinds of atoms, but differing in the bonding patterns by which the atoms are held together.

isomorphic (eye so more' fik) [Gk. *isos*: equal + *morphe*: form] Having the same form or appearance, as when the haploid and diploid life stages of an organism appear identical. (Contrast with heteromorphic.)

isotonic Having the same solute concentration; said of two solutions. (Contrast with hypertonic, hypotonic.)

isotope (eye' so tope) [Gk. *isos*: equal + *topos*: place] Isotopes of a given chemical element have the same number of protons in their nuclei (and thus are in the same position on the periodic table), but differ in the number of neutrons.

isozymes Enzymes of an organism that have somewhat different amino acid sequences but catalyze the same reaction.

iteroparous [L. *itero*, to repeat + *pario*, to beget] Reproducing multiple times in a lifetime. (Contrast with semelparous.)

J

jasmonate Also called jasmonic acid, a plant hormone involved in triggering responses to pathogen attack as well as other processes.

jejunum (jih jew' num) The middle division of the small intestine, where most absorption of nutrients occurs. (See also duodenum, ileum.)

joint In skeletal systems, a junction between two or more bones.

juvenile hormone In insects, a hormone maintaining larval growth and preventing maturation or pupation.

K

K-strategist A species whose life history strategy allows it to persist at or near the carrying capacity (*K*) of its environment. (Contrast with *r*-strategist.)

karyogamy The fusion of nuclei of two cells. (Contrast with plasmogamy.)

karyotype The number, forms, and types of chromosomes in a cell.

keystone species Species that have a dominant influence on the composition of a community.

kidneys A pair of excretory organs in vertebrates.

kilocalorie (kcal) See Calorie.

kin selection That component of inclusive fitness resulting from helping the survival of relatives containing the same alleles by descent from a common ancestor. (Contrast with direct fitness.)

kinase See protein kinase.

kinetic energy (kuh-net' ik) [Gk. *kinetos*: moving] The energy associated with movement. (Contrast with potential energy.)

kinetochore (kuh net' oh core) Specialized structure on a centromere to which microtubules attach.

knockout A molecular genetic method in which a single gene of an organism is permanently inactivated.

Koch's postulates A set of rules for establishing that a particular microorganism causes a particular disease.

Krebs cycle See citric acid cycle.

L

lagging strand In DNA replication, the daughter strand that is synthesized in discontinuous stretches. (See Okazaki fragments.)

large intestine See colon.

larva (plural: larvae) [L. *lares*: guiding spirits] An immature stage of any animal that differs dramatically in appearance from the adult.

lateral [L. *latus*: side] Pertaining to the side.

lateral gene transfer The transfer of genes from one species to another, common among bacteria and archaea.

lateral meristem Either of the two meristems, the vascular cambium and the cork cambium, that give rise to a plant's secondary growth.

lateral root A root extending outward from the taproot in a taproot system; typical of eudicots.

lateralization A phenomenon in humans in which language functions come to reside in one cerebral hemisphere, usually the left.

laticifers (luh tiss' uh furs) In some plants, elongated cells containing secondary plant products such as latex.

Laurasia The northernmost of the two large continents produced by the breakup of Pangaea.

law of independent assortment See independent assortment.

law of segregation See segregation.

laws of thermodynamics [Gk. *thermos*: heat + *dynamis*: power] Laws derived from studies of the physical properties of energy and the ways energy interacts with matter. (See also first law of thermodynamics, second law of thermodynamics.)

leaching In soils, a process by which mineral nutrients in upper soil horizons are dissolved in water and carried to deeper horizons, where they are unavailable to plant roots.

leading strand In DNA replication, the daughter strand that is synthesized continuously. (Contrast with lagging strand.)

leaf (plural: leaves) In plants, the chief organ of photosynthesis.

leaf primordium (plural: primordia) An outgrowth on the side of the shoot apical meristem that will eventually develop into a leaf.

leghemoglobin In nitrogen-fixing plants, an oxygen-carrying protein in the cytoplasm of nodule cells that transports enough oxygen to the nitrogen-fixing bacteria to support their respiration, while keeping free oxygen concentrations low enough to protect nitrogenase.

lek A display ground within which male animals compete for and defend small display areas as a means of demonstrating their territorial prowess and winning opportunities to mate.

lens In the vertebrate eye, a crystalline protein structure that makes fine adjustments in the focus of images falling on the retina.

leptin A hormone produced by fat cells that is believed to provide feedback information to the brain about the status of the body's fat reserves.

leukocyte See white blood cell.

lichen (lie' kun) An organism resulting from the symbiotic association of a fungus and either a cyanobacterium or a unicellular alga.

life cycle The entire span of the life of an organism from the moment of fertilization (or asexual generation) to the time it reproduces in turn.

life history strategy The way in which an organism partitions its time and energy among growth, maintenance, and reproduction.

life history The time course of growth and development, reproduction, and death during an average individual organism's life.

life table A summary of information about the progression of individuals in a population through the various stages of their life cycles.

life zones In the aquatic (marine and freshwater) biomes, the regions defined by light penetration and water movement such as wave action. Life zones include, e.g., the intertidal, pelagic (open water) and benthic (bottom) zones.

ligament A band of connective tissue linking two bones in a joint.

ligand (lig' and) Any molecule that binds to a receptor site of another (usually larger) molecule.

light reactions The initial phase of photosynthesis, in which light energy is converted into chemical energy. Followed by the **light-independent reactions** in which the energy captured in the light reactions is used to drive the reduction of CO₂ to form carbohydrates.

light-harvesting complex In photosynthesis, a group of different molecules that cooperate to absorb light energy and transfer it to a reaction center. Also called *antenna system*.

lignin A complex, hydrophobic polyphenolic polymer in plant cell walls that crosslinks other wall polymers, strengthening the walls, especially in wood.

limbic system A group of evolutionarily primitive structures in the vertebrate telencephalon that are involved in emotions, drives, instinctive behaviors, learning, and memory.

limiting resource The required resource whose supply (or lack thereof) most strongly influences the size of a population.

limnetic zone The open-water life zone of a lake

lineage A series of populations, species, or genes descended from a single ancestor over evolutionary time.

lineage species concept The definition of a species as a branch on the tree of life, which has a history that starts at a speciation event and ends either at extinction or at another speciation event. (Contrast with biological species concept; morphological species concept.)

linkage See genetic linkage.

lipase (lip' ase; lye' pase) An enzyme that digests fats.

lipid (lip' id) [Gk. *lipos*: fat] Nonpolar, hydrophobic molecules that include fats, oils, waxes, steroids, and the phospholipids that make up biological membranes.

lipid bilayer See phospholipid bilayer.

lipoproteins Lipids packaged inside a covering of protein so that they can be circulated in the blood.

lithosphere (lith' o sphere) [Gk. *lithos*: strong] The crust of solid rock plates that overlays the viscous mantle of Earth. The movements of the lithosphere are the source of plate tectonics. (Contrast with asthenosphere.)

littoral zone The nearshore life zone of a lake that is shallow and is affected by wave action and fluctuations in water level.

liver A large digestive gland. In vertebrates, it secretes bile and is involved in the formation of blood.

loam A type of soil consisting of a mixture of sand, silt, clay, and organic matter. One of the best soil types for agriculture.

locus (low' kus) (plural: loci, low' sigh) In genetics, a specific location on a chromosome. May be considered synonymous with *gene*.

logistic growth Growth, especially in the size of an organism or in the number of organisms in a population, that slows steadily as the entity approaches its maximum size. (Contrast with multiplicative growth.)

long-day plant (LDP) A plant that requires long days (actually, short nights) in order to flower. (Compare to short-day plant.)

long-term potentiation (LTP) A long-lasting increase in the responsiveness of a neuron resulting from a period of intense stimulation.

loop of Henle (hen' lee) Long, hairpin loop of the mammalian renal tubule that runs from the cortex down into the medulla and back to the cortex; creates a concentration gradient in the interstitial fluids in the medulla.

lophophore A U-shaped fold of the body wall with hollow, ciliated tentacles that encircles the mouth of animals in several different groups. Used for filtering prey from the surrounding water.

loss of function mutation A mutation that results in the loss of a functional protein. (Contrast with gain of function mutation.)

low-density lipoproteins (LDLs) Lipoproteins that transport cholesterol around the body for use in biosynthesis and for storage; LDLs are the "bad" lipoproteins associated with a high risk of cardiovascular disease.

lumen (loo' men) [L. *lumen*: light] The open cavity inside any tubular organ or structure, such as the gut or a renal tubule.

lung An internal organ specialized for respiratory gas exchange with air.

luteinizing hormone (LH) A gonadotropin produced by the anterior pituitary that stimulates the gonads to produce sex hormones.

lymph [L. *lymph*: liquid] A fluid derived from blood and other tissues that accumulates in intercellular spaces throughout the body and is returned to the blood by the lymphatic system.

lymph node A specialized structure in the vessels of the lymphatic system. Lymph

nodes contain lymphocytes, which encounter and respond to foreign cells and molecules in the lymph as it passes through the vessels.

lymphatic system A system of vessels that returns interstitial fluid to the blood.

lymphocyte One of the two major classes of white blood cells; includes T cells, B cells, and other cell types important in the immune system.

lysis (lie' sis) [Gk. *lysis*: break apart] Bursting of a cell.

lysogeny A form of viral replication in which the virus becomes incorporated into the host chromosome and remains inactive. Also called a lysogenic cycle. (Contrast with lytic cycle.)

lysosome (lie' so soam) [Gk. *lysis*: break away + *soma*: body] A membrane-enclosed organelle originating from the Golgi apparatus and containing hydrolytic enzymes. (Contrast with secondary lysosome.)

lysozyme (lie' so zyme) An enzyme in saliva, tears, and nasal secretions that hydrolyzes bacterial cell walls.

lytic cycle A viral reproductive cycle in which the virus takes over a host cell's synthetic machinery to replicate itself, then bursts (lyses) the host cell, releasing the new viruses. (Contrast with lysogeny.)

M

M phase The portion of the cell cycle in which mitosis takes place.

macroevolution [Gk. *makros*: large] Evolutionary changes occurring over long time spans and usually involving changes in many traits. (Contrast with microevolution.)

macromolecule A giant (molecular weight > 1,000) polymeric molecule. The macromolecules are the proteins, polysaccharides, and nucleic acids.

macronutrient In plants, a mineral element required in concentrations of at least 1 milligram per gram of plant dry matter; in animals, a mineral element required in large amounts. (Contrast with micronutrient.)

macrophage (mac' roh faj) Phagocyte that engulfs pathogens by endocytosis.

MADS box DNA-binding domain in many plant transcription factors that is active in development.

maintenance methylase An enzyme that catalyzes the methylation of the new DNA strand when DNA is replicated.

major histocompatibility complex (MHC) A complex of linked genes, with multiple alleles, that control a number of cell surface antigens that identify self and can lead to graft rejection.

malignant Pertaining to a tumor that can grow indefinitely and/or spread from the original site of growth to other locations in the body. (Contrast with benign.)

malnutrition A condition caused by lack of any essential nutrient.

Malpighian tubule (mal pee' gy un) A type of protonephridium found in insects.

mantle (1) In mollusks, a fold of tissue that covers the organs of the visceral mass and secretes the hard shell that is typical of many mollusks. (2) In geology, the Earth's crust below the solid lithospheric plates.

map unit The distance between two genes as calculated from genetic crosses; a recombination frequency.

marine [L. *mare*: sea, ocean] Pertaining to or living in the ocean. (Contrast with aquatic, terrestrial.)

mark-recapture method A method of estimating population sizes of mobile organisms by capturing, marking, and releasing a sample of individuals, then capturing another sample at a later time.

mass extinction A period of evolutionary history during which rates of extinction are much higher than during intervening times.

mass number The sum of the number of protons and neutrons in an atom's nucleus.

mast cells Cells, typically found in connective tissue, that release histamine in response to tissue damage.

maternal effect genes Genes coding for morphogens that determine the polarity of the egg and larva in fruit flies. Part of a developmental cascade that includes gap genes, pair rule genes, segment polarity genes, and Hox genes.

mating type A particular strain of a species that is incapable of sexual reproduction with another member of the same strain but capable of sexual reproduction with members of other strains of the same species.

maturational survivorship curves *See* survivorship curves

maximum likelihood A statistical method of determining which of two or more hypotheses (such as phylogenetic trees) best fit the observed data, given an explicit model of how the data were generated.

mechanically gated channel A molecular channel that opens or closes in response to mechanical force applied to the plasma membrane in which it is inserted.

mechanoreceptor A cell that is sensitive to physical movement and generates action potentials in response.

medulla (meh dull' luh) (1) The inner, core region of an organ, as in the adrenal medulla (adrenal gland) or the renal medulla (kidneys). (2) The portion of the brainstem that connects to the spinal cord.

medusa (plural: medusae) In cnidarians, a free-swimming, sexual life cycle stage shaped like a bell or an umbrella.

megagametophyte In heterosporous plants, the female gametophyte; produces eggs. (Contrast with microgametophyte.)

megaphyll The generally large leaf of a fern, horsetail, or seed plant, with several to many veins. (Contrast with microphyll.)

megaspore [Gk. *megas*: large + *spora*: to sow] In plants, a haploid spore that produces a female gametophyte.

megastrobilus In conifers, the female (seed-bearing) cone. (Contrast with microstrobilus.)

meiosis (my oh' sis) [Gk. *meiosis*: diminution] Division of a diploid nucleus to produce four haploid daughter cells. The process consists of two successive nuclear divisions with only one cycle of chromosome replication. In *meiosis I*, homologous chromosomes separate but retain their chromatids. The second division *meiosis II*, is similar to mitosis, in which chromatids separate.

melatonin A hormone released by the pineal gland. Involved in photoperiodicity and circadian rhythms.

membrane A phospholipid bilayer forming a barrier that separates the internal contents of a cell from the nonbiological environment, or enclosing the organelles within a cell. The membrane regulates the molecular substances entering or leaving a cell or organelle.

membrane potential The difference in electrical charge between the inside and the outside of a cell, caused by a difference in the distribution of ions.

membranous bone A type of bone that develops by forming on a scaffold of connective tissue. (Contrast with cartilage bone.)

memory cells Long-lived lymphocytes produced after exposure to antigen. They persist in the body and are able to mount a rapid response to subsequent exposures to the antigen.

Mendel's laws See independent assortment; segregation.

menopause In human females, the end of fertility and menstrual cycling.

menstruation The process by which the endometrium breaks down, and the sloughed-off tissue, including blood, flows from the body.

meristem [Gk. *meristos*: divided] Plant tissue made up of undifferentiated actively dividing cells.

meristem culture A method for the asexual propagation of plants, in which pieces of shoot apical meristem are cultured to produce plantlets.

meristem identity genes In angiosperms, a group of genes whose expression initiates flower formation, probably by switching meristem cells from a vegetative to a reproductive fate.

mesenchyme (mez' en kyme) [Gk. *mesos*: middle + *enchyma*: infusion] Embryonic or unspecialized cells derived from the mesoderm.

mesoderm [Gk. *mesos*: middle + *derma*: skin] The middle of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skeleton, circulatory system,

muscles, excretory system, and most of the reproductive system.

mesoglea (mez' uh glee uh) [Gk. *mesos*: middle + *gloia*, glue] A thick, gelatinous noncellular layer that separates the two cellular tissue layers of ctenophores, cnidarians, and scyphozoans.

mesophyll (mez' uh fill) [Gk. *mesos*: middle + *phyllon*: leaf] Chloroplast-containing, photosynthetic cells in the interior of leaves.

messenger RNA (mRNA) Transcript of a region of one of the strands of DNA; carries information (as a sequence of codons) for the synthesis of one or more proteins.

meta- [Gk.: between, along with, beyond] Prefix denoting a change or a shift to a new form or level; for example, as used in metamorphosis.

metabolic pathway A series of enzyme-catalyzed reactions so arranged that the product of one reaction is the substrate of the next.

metabolism (meh tab' a lizm) [Gk. *metabole*: change] The sum total of the chemical reactions that occur in an organism, or some subset of that total (as in respiratory metabolism).

metabolome The quantitative description of all the small molecules in a cell or organism.

metabotropic receptor A receptor that that indirectly alters membrane permeability to a type of ion when it combines with its ligand.

metagenomics The practice of analyzing DNA from environmental samples without isolating intact organisms.

metamorphosis (met' a mor' fo sis) [Gk. *meta*: between + *morphe*: form, shape] A change occurring between one developmental stage and another, as for example from a tadpole to a frog. (See complete metamorphosis, incomplete metamorphosis.)

metanephridia The paired excretory organs of annelids.

metaphase (met' a phase) The stage in nuclear division at which the centromeres of the highly supercoiled chromosomes are all lying on a plane (the metaphase plane or plate) perpendicular to a line connecting the division poles.

metapopulation A population divided into subpopulations, among which there are occasional exchanges of individuals.

methylation The addition of a methyl group ($-\text{CH}_3$) to a molecule.

MHC See major histocompatibility complex.

micelle A particle of lipid covered with bile salts that is produced in the duodenum and facilitates digestion and absorption of lipids.

microbiomes The diverse communities of bacteria that live on or within the body and are essential to bodily function.

microclimate A subset of climatic conditions in a small specific area, which generally differ from those in the

environment at large, as in an animal's underground burrow.

microevolution Evolutionary changes below the species level, affecting allele frequencies. (Contrast with macroevolution.)

microfibril Crosslinked cellulose polymers, forming strong aggregates in the plant cell wall.

microfilament In eukaryotic cells, a fibrous structure made up of actin monomers. Microfilaments play roles in the cytoskeleton, in cell movement, and in muscle contraction.

microgametophyte In heterosporous plants, the male gametophyte; produces sperm. (Contrast with megagametophyte.)

microglia Glial cells that act as macrophages and mediators of inflammatory responses in the central nervous system.

micronutrient In plants, a mineral element required in concentrations of less than 100 micrograms per gram of plant dry matter; in animals, a mineral element required in concentrations of less than 100 micrograms per day. (Contrast with macronutrient.)

microphyll A small leaf with a single vein, found in club mosses and their relatives. (Contrast with megaphyll.)

micropyle (mike' roh pile) [Gk. *mikros*: small + *pylon*: gate] Opening in the integument(s) of a seed plant ovule through which pollen grows to reach the female gametophyte within.

microRNA A small, noncoding RNA molecule, typically about 21 bases long, that binds to mRNA to inhibit its translation.

microspore [Gk. *mikros*: small + *spora*: to sow] In plants, a haploid spore that produces a male gametophyte.

microstrobilus In conifers, male pollen-bearing cone. (Contrast with megastrobilus.)

microtubules Tubular structures found in centrioles, spindle apparatus, cilia, flagella, and cytoskeleton of eukaryotic cells. These tubules play roles in the motion and maintenance of shape of eukaryotic cells.

microvilli (sing.: microvillus) Projections of epithelial cells, such as the cells lining the small intestine, that increase their surface area.

midbrain One of the three regions of the vertebrate brain. Part of the brainstem, it serves as a relay station for sensory signals sent to the cerebral hemispheres.

middle lamella (la mell' ah) [L. *lamina*: thin sheet] A layer of polysaccharides that separates plant cells; a shared middle lamella lies outside the primary walls of the two cells.

mineral nutrients Inorganic ions required by organisms for normal growth and reproduction.

mismatch repair A mechanism that scans DNA after it has been replicated and corrects any base-pairing mismatches.

missense mutation A change in a gene's sequence that changes the amino acid at that site in the encoded protein. (Contrast with

frame-shift mutation, nonsense mutation, silent mutation.)

mitochondria (my' toe kon' drie uh) (singular: mitochondrion) [Gk. *mitos*: thread + *chondros*: grain] Energy-generating organelles in eukaryotic cells that contain the enzymes of the citric acid cycle, the respiratory chain, and oxidative phosphorylation.

mitochondrial matrix The fluid interior of a mitochondrion, enclosed by the inner mitochondrial membrane.

mitosis (my toe' sis) [Gk. *mitos*: thread] Nuclear division in eukaryotes leading to the formation of two daughter nuclei, each with a chromosome complement identical to that of the original nucleus.

mitosomes Reduced structures derived from mitochondria found in some organisms.

model systems Also known as **model organisms**, these include the small group of species that are the subject of extensive research. They are organisms that adapt well to laboratory situations and findings from experiments on them can apply across a broad range of species. Classic examples include white mice and the fruit fly *Drosophila*.

moderately repetitive sequences DNA sequences repeated 10–1,000 times in the eukaryotic genome. They include the genes that code for rRNAs and tRNAs, as well as the DNA in telomeres.

Modern Synthesis An understanding of evolutionary biology that emerged in the early twentieth century as the principles of evolution were integrated with the principles of modern genetics.

modularity In evolutionary developmental biology, the principle that the molecular pathways that determine different developmental processes operate independently from one another. *See also* developmental module.

mole A quantity of a compound whose weight in grams is numerically equal to its molecular weight expressed in atomic mass units. Avogadro's number of molecules: 6.023×10^{23} molecules.

molecular clock The approximately constant rate of divergence of macromolecules from one another over evolutionary time; used to date past events in evolutionary history.

molecular evolution The scientific study of the mechanisms and consequences of the evolution of macromolecules.

molecular toolkit *See* genetic toolkit.

molecular weight The sum of the atomic weights of the atoms in a molecule.

molecule A chemical substance made up of two or more atoms joined by covalent bonds or ionic attractions.

molting The process of shedding part or all of an outer covering, as the shedding of feathers by birds or of the entire exoskeleton by arthropods.

monoclonal antibody Antibody produced in the laboratory from a clone of hybridoma cells, each of which produces the same specific antibody.

monocots Angiosperms with a single embryonic cotyledon; one of the two largest clades of angiosperms. (*See also* eudicots.)

monoculture In agriculture, a large-scale planting of a single species of domesticated crop plant.

monoecious (mo nee' shus) [Gk. *mono*: one + *oikos*: house] Pertaining to organisms in which both sexes are "housed" in a single individual that produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples include corn, peas, earthworms, hydras. (Contrast with dioecious.)

monohybrid cross A mating in which the parents differ with respect to the alleles of only one locus of interest.

monomer [Gk. *mono*: one + *meros*: unit] A small molecule, two or more of which can be combined to form oligomers (consisting of a few monomers) or polymers (consisting of many monomers).

monophyletic (mon' oh fih leht' ik) [Gk. *mono*: one + *phylon*: tribe] Pertaining to a group that consists of an ancestor and all of its descendants. (Contrast with paraphyletic, polyphyletic.)

monosaccharide A simple sugar. Oligosaccharides and polysaccharides are made up of monosaccharides.

monosomic Pertaining to an organism with one less than the normal diploid number of chromosomes.

monosynaptic reflex A neural reflex that begins in a sensory neuron and makes a single synapse before activating a motor neuron.

morphogen A diffusible substance whose concentration gradient determines a developmental pattern in embryonic animals and plants.

morphogenesis (more' fo jen' e sis) [Gk. *morphe*: form + *genesis*: origin] The development of form; the overall consequence of determination, differentiation, and growth.

morphological species concept The definition of a species as a group of individuals that look alike. (Contrast with biological species concept; lineage species concept.)

morphology (more fol' o jee) [Gk. *morphe*: form + *logos*: study, discourse] The scientific study of organic form, including both its development and function.

mortality Death, or the death rate of a population.

mosaic development Pattern of animal embryonic development in which each blastomere contributes a specific part of the adult body. (Contrast with regulative development.)

motif *See* structural motif.

motile (mo' tul) Able to move from one place to another. (Contrast with sessile.)

motor cortex The region of the cerebral cortex that contains motor neurons that directly stimulate specific muscle fibers to contract.

motor end plate The depression in the postsynaptic membrane of the neuromuscular junction where the terminals of the motor neuron sit.

motor neuron A neuron carrying information from the central nervous system to a cell that produces movement.

motor proteins Specialized proteins that use energy to change shape and move cells or structures within cells.

motor unit A motor neuron and the muscle fibers it controls.

mouth An opening through which food is taken in, located at the anterior end of a tubular gut.

mRNA *See* messenger RNA.

mucosal epithelium An epithelial cell layer containing cells that secrete mucus; found in the digestive and respiratory tracts. Also called mucosa.

mucus A viscous substance secreted by mucous membranes (e.g., mucosal epithelium). A barrier defense against pathogens in innate immunity in animals and a protective coating in many animal organ systems.

Muller's ratchet The accumulation—"ratcheting up"—of deleterious mutations in the nonrecombining genomes of asexual species.

Müllerian mimicry Convergence in appearance of two or more unpalatable species.

multifactorial The interaction of many genes and proteins with one or more factors in the environment. For example, cancer is a disease with multifactorial causes.

multipotent Having the ability to differentiate into a limited number of cell types. (Contrast with pluripotent, totipotent.)

muscle fiber A single muscle cell. In the case of skeletal muscle, a syncytial, multinucleate cell.

muscle tissue Excitable tissue that can contract through the interactions of actin and myosin; one of the four major tissue types in multicellular animals. There are three types of muscle tissue: skeletal, smooth, and cardiac.

mutagen (mute' ah jen) [L. *mutare*: change + Gk. *genesis*: source] Any agent (e.g., a chemical, radiation) that increases the mutation rate.

mutation A change in the genetic material not caused by recombination.

mutualism A type of interaction between species that benefits both species.

mycelium (my seel' ee yum) [Gk. *mykes*: fungus] In the fungi, a mass of hyphae.

mycologists Scientists who study fungi.

mycorrhiza (my' ko rye' za) (plural: mycorrhizae) [Gk. *mykes*: fungus + *rhiza*: root] An association of the root of a plant with the mycelium of a fungus.

myelin (my' a lin) Concentric layers of plasma membrane that form a sheath around some axons; myelin provides the axon with electrical insulation and increases the rate of transmission of action potentials.

myocardial infarction (MI) Blockage of an artery that carries blood to the heart muscle; a "heart attack."

MyoD The protein encoded by the *myoblast* determining gene. A transcription factor involved in the differentiation of myoblasts (muscle precursor cells).

myofibril (my' oh fy' bril) [Gk. *mys*: muscle + L. *fibrilla*: small fiber] A polymeric unit of actin or myosin in a muscle.

myoglobin (my' oh globe' in) [Gk. *mys*: muscle + L. *globus*: sphere] An oxygen-binding molecule found in muscle. Consists of a heme unit and a single globin chain; carries less oxygen than hemoglobin.

myosin One of the two contractile proteins of muscle. See also actin.

N

natural history The characteristics of a group of organisms, such as how the organisms get their food, reproduce, behave, regulate their internal environments (their cells, tissues, and organs), and interact with other organisms.

natural killer cell A type of lymphocyte that attacks virus-infected cells and some tumor cells as well as antibody-labeled target cells.

natural selection The differential contribution of offspring to the next generation by various genetic types belonging to the same population. The mechanism of evolution proposed by Charles Darwin.

nauplius (naw' plee us) [Gk. *nauplios*: shellfish] A bilaterally symmetrical larval form typical of crustaceans.

necrosis (nec roh' sis) [Gk. *nekros*: death] Premature cell death caused by external agents such as toxins.

negative feedback In regulatory systems, information that decreases a regulatory response, returning the system to the set point. (Contrast with positive feedback.)

negative regulation A type of gene regulation in which a gene is normally transcribed, and the binding of a repressor protein to the promoter prevents transcription. (Contrast with positive regulation.)

nematocyst (ne mat' o sist) [Gk. *nema*: thread + *kystis*: cell] An elaborate, threadlike structure produced by cells of jellyfishes and other cnidarians, used chiefly to paralyze and capture prey.

neoteny (knee ot' enny) [Gk. *neo*: new, recent; *tenein*, to extend] The retention of

juvenile or larval traits by the fully developed adult organism.

nephron (nef' ron) [Gk. *nephros*: kidney] The functional unit of the kidney, consisting of a structure for receiving a filtrate of blood and a tubule that reabsorbs selected parts of the filtrate.

Nernst equation A mathematical statement that calculates the potential across a membrane permeable to a single type of ion that differs in concentration on the two sides of the membrane.

nerve A structure consisting of many neuronal axons and connective tissue.

nerve nets Diffuse, loosely connected aggregations of nervous tissues in certain non-bilaterialian animals such as cnidarians.

nervous tissue Tissue specialized for processing and communicating information; one of the four major tissue types in multicellular animals.

net primary productivity (NPP) The rate at which energy captured by photosynthesis is incorporated into the bodies of primary producers through growth and reproduction.

neural crest cells During vertebrate neurulation, cells that migrate outward from the neural plate and give rise to connections between the central nervous system and the rest of the body.

neural network An organized group of neurons that contains three functional categories of neurons—afferent neurons, interneurons, and efferent neurons—and is capable of processing information.

neural tube An early stage in the development of the vertebrate nervous system consisting of a hollow tube created by two opposing folds of the dorsal ectoderm along the anterior–posterior body axis.

neurohormone A chemical signal produced and released by neurons that subsequently acts as a hormone.

neuromuscular junction Synapse (point of contact) where a motor neuron axon stimulates a muscle fiber cell.

neuron (noor' on) [Gk. *neuron*: nerve] A nervous system cell that can generate and conduct action potentials along an axon to a synapse with another cell.

neurotransmitter A substance produced in and released by a neuron (the presynaptic cell) that diffuses across a synapse and excites or inhibits another cell (the postsynaptic cell).

neurulation Stage in vertebrate development during which the nervous system begins to form.

neutral allele An allele that does not alter the functioning of the proteins for which it codes.

neutral theory A view of molecular evolution that postulates that most mutations do not affect the amino acid being coded for, and that such mutations accumulate in a population at rates driven by genetic drift and mutation rates.

neutron (new' tron) One of the three fundamental particles of matter (along with protons and electrons), with mass slightly larger than that of a proton and no electrical charge.

niche (nitch) [L. *nidus*: nest] The set of physical and biological conditions a species requires to survive, grow, and reproduce.

nitrate reduction The process by which nitrate (NO_3^-) is reduced to ammonia (NH_3).

nitric oxide (NO) An unstable molecule (a gas) that serves as a second messenger causing smooth muscle to relax. In the nervous system it operates as a neurotransmitter.

nitrification The oxidation of ammonia (NH_3) to nitrate (NO_3^-) in soil and seawater, carried out by chemoautotrophic bacteria (nitrifiers).

nitrogen fixation Conversion of atmospheric nitrogen gas (N_2) into a more reactive and biologically useful form (ammonia), which makes nitrogen available to living things. Carried out by **nitrogen fixers**—bacteria, some of them free-living and others living within plant roots.

nitrogenase An enzyme complex found in nitrogen-fixing bacteria that mediates the stepwise reduction of atmospheric N_2 to ammonia and which is strongly inhibited by oxygen.

nitrogenous wastes The potentially toxic nitrogen-containing end products—ammonia, urea, or uric acid—of protein and nucleic acid catabolism in animals. Eliminated from the body by excretion.

node [L. *nodus*: knob, knot] In plants, a (sometimes enlarged) point on a stem where a leaf is or was attached.

node of Ranvier A gap in the myelin sheath covering an axon; the point where the axonal membrane can fire action potentials.

nodule A specialized structure in the roots of nitrogen-fixing plants that houses nitrogen-fixing bacteria, in which oxygen is maintained at a low level by leghemoglobin.

non-REM sleep A state of deep, restorative sleep characterized by high-amplitude slow waves in the EEG. (Contrast with REM sleep.)

noncompetitive inhibitor A nonsubstrate that inhibits the activity of an enzyme by binding to a site other than its active site. (Contrast with competitive inhibitor.)

noncyclic electron transport In photosynthesis, the flow of electrons that forms ATP, NADPH, and O_2 .

nondisjunction Failure of sister chromatids to separate in meiosis II or mitosis, or failure of homologous chromosomes to separate in meiosis I. Results in aneuploidy.

nonpolar Having electric charges that are evenly balanced from one end to the other. (Contrast with polar.)

nonrandom mating Selection of mates on the basis of a particular trait or group of traits.

nonsense mutation Change in a gene's sequence that prematurely terminates translation by changing one of its codons to a stop codon.

nonsynonymous substitution A change in a gene from one nucleotide to another that changes the amino acid specified by the corresponding codon (i.e., AGC → AGA, or serine → arginine). (Contrast with synonymous substitution.)

norepinephrine A neurotransmitter found in the central nervous system and also at the postganglionic nerve endings of the sympathetic nervous system. Also called noradrenaline.

normal flora Microorganisms that normally live and reproduce on or in the body without causing disease, and which form a nonspecific defense against pathogens by competing with them for space and nutrients. See also microbiota.

notochord (no' tow kord) [Gk. *notos*: back + *chorde*: string] A flexible rod of gelatinous material serving as a support in the embryos of all chordates and in the adults of tunicates and lancelets.

nucleic acid (new klay' ik) A polymer made up of nucleotides, specialized for the storage, transmission, and expression of genetic information. DNA and RNA are nucleic acids.

nucleic acid hybridization A technique in which a single-stranded nucleic acid probe is made that is complementary to, and binds to, a target sequence, either DNA or RNA. The resulting double-stranded molecule is a hybrid.

nucleoid (new' klee oid) The region that harbors the chromosomes of a prokaryotic cell. Unlike the eukaryotic nucleus, it is not bounded by a membrane.

nucleolus (new klee' oh lus) A small, generally spherical body found within the nucleus of eukaryotic cells. The site of synthesis of ribosomal RNA.

nucleoside A nucleotide without the phosphate group; a nitrogenous base attached to a sugar.

nucleosome A portion of a eukaryotic chromosome, consisting of part of the DNA molecule wrapped around a group of histone molecules, and held together by another type of histone molecule. The chromosome is made up of many nucleosomes.

nucleotide The basic chemical unit in nucleic acids, consisting of a pentose sugar, a phosphate group, and a nitrogen-containing base.

nucleotide substitution A change of one base pair to another in a DNA sequence.

nucleus (new' klee us) [L. *nux*: kernel or nut] (1) In cells, the centrally located compartment of eukaryotic cells that is bounded by a double membrane and contains the chromosomes. (2) In the brain, an identifiable group of neurons that share common characteristics or functions.

null hypothesis In statistics, the premise that any differences observed in an

experiment are simply the result of random differences that arise from drawing two finite samples from the same population.

nutrient A food substance; or, in the case of mineral nutrients, an inorganic element required for completion of the life cycle of an organism.

O

obligate anaerobe An anaerobic prokaryote that cannot survive exposure to O₂.

occipital lobe One of the four lobes of the brain's cerebral hemisphere; processes visual information.

odorant A molecule that can bind to an olfactory receptor.

oil A triglyceride that is liquid at room temperature. (Contrast with fat.)

Okazaki fragments Newly formed DNA making up the lagging strand in DNA replication. DNA ligase links Okazaki fragments together to give a continuous strand.

olfaction (ole fak' shun) [L. *olfacere*: to smell] The sense of smell.

olfactory bulb Structure in the vertebrate forebrain that receives and processes input from olfactory receptor neurons.

olfactory receptor neurons (ORNs) Neurons with receptors for different odorants.

oligodendrocyte A type of glial cell that myelinates axons in the central nervous system.

oligophagous [Gk. *oligo*: few; *phagein*, eat] An animal that feeds on a limited number of foods; generally used of insects that feed on only one or a few plant species.

oligosaccharide A polymer containing a small number of monosaccharides.

omasum One of the four chambers of the stomach in ruminants; concentrates food by water absorption before it enters the true stomach (abomasum).

ommatidia [Gk. *omma*: eye] The units that make up the compound eye of some arthropods.

omnivore [L. *omnis*: everything + *vorare*: to devour] An organism that eats both animal and plant material. (Contrast with carnivore, detritivore, herbivore.)

oncogene [Gk. *onkos*: mass, tumor + *genes*: born] A gene that codes for a protein product that stimulates cell proliferation. Mutations in oncogenes that result in excessive cell proliferation can give rise to cancer.

one gene—one polypeptide The idea, now known to be an oversimplification, that each gene in the genome encodes only a single polypeptide—that there is a one-to-one correspondence between genes and polypeptides.

oocyte See primary oocyte, secondary oocyte.

oogenesis (oh' eh jen e sis) [Gk. *oon*: egg + *genesis*: source] Gametogenesis leading to production of an ovum.

oogonium (oh' eh go' nee um) (plural: oogonia) (1) In some algae and fungi, a cell in which an egg is produced. (2) In animals, the diploid progeny of a germ cell in females.

ootid In oogenesis, the daughter cell of the second meiotic division that differentiates into the mature ovum.

open circulatory system Circulatory system in which extracellular fluid leaves the vessels of the circulatory system, percolates between cells and through tissues, and then flows back into the circulatory system to be pumped out again. (Contrast with closed circulatory system.)

operator The region of an operon that acts as the binding site for the repressor.

operon A genetic unit of transcription, typically consisting of several structural genes that are transcribed together; the operon contains at least two control regions: the promoter and the operator.

opportunity cost The sum of the benefits an animal forfeits by not being able to perform some other behavior during the time when it is performing a given behavior.

opsin (op' sin) [Gk. *opsis*: sight] The protein portion of vertebrate visual pigments; associated with the pigment molecule 11-*cis*-retinal. See also rhodopsin.

optic chiasm [Gk. *chiasma*: cross] Structure on the lower surface of the vertebrate brain where the two optic nerves come together.

optic nerve The nerve that carries information from the retina of the eye to the brain.

optical isomers Two molecular isomers that are mirror images of each other.

optimal foraging theory The application of a cost-benefit approach to feeding behavior to identify the fitness value of feeding choices.

oral [L. *os*: mouth] Pertaining to the mouth, or that part of the body that contains the mouth.

orbital A region in space surrounding the atomic nucleus in which an electron is most likely to be found.

organ [Gk. *organon*: tool] A body part, such as the heart, liver, brain, root, or leaf. Organs are composed of different tissues integrated to perform a distinct function. Organs, in turn, are integrated into organ systems.

organ identity genes In angiosperms, genes that specify the different organs of the flower. (Compare with homeotic genes.)

organ of Corti Structure in the inner ear that transforms mechanical forces produced from pressure waves ("sound waves") into action potentials that are sensed as sound.

organ system An interrelated and integrated group of tissues and organs that work together in a physiological function.

organelle (or gan el') Any of the membrane-enclosed structures within a eukaryotic cell. Examples include the nucleus, endoplasmic reticulum, and mitochondria.

organic (1) Pertaining to any chemical compound that contains carbon. (2) Pertaining to any aspect of living matter, e.g., to its evolution, structure, or chemistry.

organic fertilizers Substances added to soil to improve the soil's fertility; derived from partially decomposed plant material (compost) or animal waste (manure).

organism Any living entity.

organizer Region of the early amphibian embryo that directs early embryonic development. Also known as the primary embryonic organizer.

organogenesis The formation of organs and organ systems during development.

origin of replication (ori) DNA sequence at which helicase unwinds the DNA double helix and DNA polymerase binds to initiate DNA replication.

orthologs [Gk. *ortho*: true, direct] Homologous genes whose divergence can be traced to speciation events.

osmoconformer An aquatic animal that equilibrates the osmolarity of its extracellular fluid to be the same as that of the external environment. (Contrast with osmoregulator.)

osmolarity The concentration of osmotically active particles in a solution.

osmoregulation Regulation of the chemical composition of the body fluids of an organism.

osmoregulator An aquatic animal that actively regulates the osmolarity of its extracellular fluid. (Contrast with osmoconformer.)

osmosis (oz mo' sis) [Gk. *osmos*: to push] Movement of water across a differentially permeable membrane, from one region to another region where the water potential is more negative.

ossicle (oss' ick ul) [L. *os*: bone] The calcified construction unit of echinoderm skeletons.

osteoblast (oss' tee oh blast) [Gk. *osteon*: bone + *blastos*: sprout] A cell that lays down the protein matrix of bone.

osteoclast (oss' tee oh clast) [Gk. *osteon*: bone + *klastos*: broken] A cell that dissolves bone.

osteocyte An osteoblast that has become enclosed in lacunae within the bone it has built.

outgroup In phylogenetics, a group of organisms used as a point of reference for comparison with the groups of primary interest (the ingroup).

oval window The flexible membrane that, when moved by the bones of the middle ear, produces pressure waves in the inner ear.

ovarian cycle In human females, the monthly cycle of events by which eggs and

hormones are produced. (Contrast with uterine cycle).

ovary (oh' var ee) [L. *ovum*: egg] Any female organ, in plants or animals, that produces an egg.

overtopping Plant growth pattern in which one branch differentiates from and grows beyond the others.

oviduct In mammals, the tube serving to transport eggs to the uterus or to the outside of the body.

oviparity Reproduction in which eggs are released by the female and development is external to the mother's body. (Contrast with viviparity.)

ovoviviparity Pertaining to reproduction in which fertilized eggs develop and hatch within the mother's body but are not attached to the mother by means of a placenta.

ovulation Release of an egg from an ovary.

ovule (oh' vule) In plants, a structure comprising the megasporangium and the integument, which develops into a seed after fertilization.

ovum (oh' vum) (plural: ova) [L. egg] The female gamete.

oxidation (ox i day' shun) Relative loss of electrons in a chemical reaction; either outright removal to form an ion, or the sharing of electrons with substances having a greater affinity for them, such as oxygen. Most oxidations, including biological ones, are associated with the liberation of energy. (Contrast with reduction.)

oxidation-reduction (redox) reaction A reaction in which one substance transfers one or more electrons to another substance. (See oxidation; reduction.)

oxidative phosphorylation ATP formation in the mitochondrion, associated with flow of electrons through the respiratory chain.

oxygenase An enzyme that catalyzes the addition of oxygen to a substrate from O₂.

oxytocin A hormone released by the posterior pituitary that promotes social bonding.

ozone layer A layer of ozone (O₃, a greenhouse gas) in the atmosphere that absorbs a high portion of the sun's potentially mutagenic ultraviolet radiation.

P

pacemaker cells Cardiac cells that can initiate action potentials without stimulation from the nervous system, allowing the heart to initiate its own contractions.

pair rule genes In *Drosophila* (fruit fly) development, segmentation genes that divide the early embryo into units of two segments each. Part of a developmental cascade that includes maternal effect genes, gap genes, segment polarity genes, and Hox genes.

paleomagnetic dating A method for determining the age of rocks based on properties relating to changes in the patterns of Earth's magnetism over time.

pancreas (pan' cree us) A gland located near the stomach of vertebrates that secretes digestive enzymes into the small intestine and releases insulin into the bloodstream.

Pangaea (pan jee' uh) [Gk. *pan*: all, every] The single land mass formed when all the continents came together in the Permian period.

para- [Gk. *para*: akin to, beside] Prefix indicating association in being along side or accessory to.

parabronchi Passages in the lungs of birds through which air flows.

paracrine [Gk. *para*: near] Pertaining to a chemical signal, such as a hormone, that acts locally, near the site of its secretion. (Contrast with autocrine.)

parallel evolution The repeated evolution of similar traits, especially among closely related species; facilitated by conserved developmental genes.

paralogs Homologous genes whose divergence can be traced to gene duplication events. (Contrast with orthologs.)

paraphyletic (par' a fih leht' ik) [Gk. *para*: beside + *phylon*: tribe] Pertaining to a group that consists of an ancestor and some, but not all, of its descendants. (Contrast with monophyletic, polyphyletic.)

parasite An organism that consumes parts of an organism much larger than itself (known as its host). Parasites sometimes, but not always, kill their host.

parasympathetic nervous system The division of the autonomic nervous system that works in opposition to the sympathetic nervous system. (Contrast with sympathetic nervous system.)

parathyroid glands Four glands on the posterior surface of the thyroid gland that produce and release parathyroid hormone.

parathyroid hormone (PTH) A hormone secreted by the parathyroid glands that stimulates osteoclast activity and raises blood calcium levels. Also called parathormone.

parenchyma (pair eng' kyma) A plant tissue composed of relatively unspecialized cells without secondary walls.

parent rock The soil horizon consisting of the rock that is breaking down to form the soil. Also called bedrock, or the C horizon.

parental (P) generation The individuals that mate in a genetic cross. Their offspring are the first filial (F₁) generation.

parietal cells One of three types of secretory cell found in the gastric pits of the stomach wall. Parietal cells produce hydrochloric acid (HCl), creating an acidic environment that destroys many of the harmful microorganisms ingested with food. (See chief cells; mucosal epithelium.)

parietal lobe One of four lobes of the cerebral hemisphere; processes complex stimuli and includes the primary somatosensory cortex.

parsimony Preferring the simplest among a set of plausible explanations of any phenomenon.

parthenocarp Formation of fruit from a flower without fertilization.

parthenogenesis [Gk. *parthenos*: virgin] Production of an organism from an unfertilized egg.

particulate theory In genetics, the theory that genes are physical entities that retain their identities after fertilization.

passive transport Diffusion across a membrane; may or may not require a channel or carrier protein. (Contrast with active transport.)

patch clamping Technique for isolating a tiny patch of membrane to allow the study of ion movement through a particular channel.

pathogen (path' o jen) [Gk. *pathos*: suffering + *genesis*: source] An organism that causes disease.

pattern formation In animal embryonic development, the organization of differentiated tissues into specific structures such as wings.

pedigree The pattern of transmission of a genetic trait within a family.

pelagic zone [Gk. *pelagos*: deep sea] The open ocean; a marine life zone.

penetrance The proportion of individuals with a particular genotype that show the expected phenotype.

penis An accessory sex organ of male animals that enables the male to deposit sperm in the female's reproductive tract.

pentaradial symmetry Symmetry in five or multiples of five; a feature of adult echinoderms.

pentose [Gk. *penta*: five] A sugar containing five carbon atoms.

PEP carboxylase The enzyme that combines carbon dioxide with PEP to form a 4-carbon dicarboxylic acid at the start of C₄ photosynthesis or of crassulacean acid metabolism (CAM).

pepsin [Gk. *pepsis*: digestion] An enzyme in gastric juice that digests protein.

pepsinogen Inactive secretory product that is converted into pepsin by low pH or by enzymatic action.

peptide hormones Relatively large hormone molecules made up of amino acids; encoded by genes and produced by translation.

peptide linkage The bond between amino acids in a protein; formed between a carboxyl group and amino group (—CO—NH—) with the loss of water molecules.

peptidoglycan The cell wall material of many bacteria, consisting of a single enormous molecule that surrounds the entire cell.

peptidyl transferase A catalytic function of the large ribosomal subunit that consists of two reactions: breaking the bond between

an amino acid and its tRNA in the P site, and forming a peptide bond between that amino acid and the amino acid attached to the tRNA in the A site.

per capita birth rate (b) In population growth models, the number of offspring that an average individual produces in some time interval.

per capita death rate (d) In population growth models, the average individual's chance of dying in some time interval.

per capita growth rate (r) In population models, the average individual's contribution to total population growth rate.

perennial (per ren' ee al) [L. *per*: throughout + *annus*: year] A plant that survives from year to year. (Contrast with annual, biennial.)

perfect flower A flower with both stamens and carpels; a hermaphroditic flower. (Contrast with imperfect flower.)

pericycle [Gk. *peri*: around + *kyklos*: ring or circle] In plant roots, tissue just within the endodermis, but outside of the root vascular tissue. Meristematic activity of pericycle cells produces lateral root primordia.

periderm The outer tissue of the secondary plant body, consisting primarily of cork.

period (1) A category in the geological time scale. (2) The duration of a single cycle in a cyclical event, such as a circadian rhythm.

peripheral membrane proteins Proteins associated with but not embedded within the plasma membrane. (Contrast with integral membrane proteins.)

peripheral nervous system (PNS) The portion of the nervous system that transmits information to and from the central nervous system, consisting of neurons that extend or reside outside the brain or spinal cord and their supporting cells. (Contrast with central nervous system.)

peristalsis (pair' i stall' sis) Wavelike muscular contractions proceeding along a tubular organ, propelling the contents along the tube.

peritoneum The mesodermal lining of the body cavity in coelomate animals.

peroxisome An organelle that houses reactions in which toxic peroxides are formed and then converted to water.

petal [Gk. *petalon*: spread out] In an angiosperm flower, a sterile modified leaf, nonphotosynthetic, frequently brightly colored, and often serving to attract pollinating insects.

petiole (pet' ee ole) [L. *petiolus*: small foot] The stalk of a leaf.

P_{fr} See phytochrome.

pH The negative logarithm of the hydrogen ion concentration; a measure of the acidity of a solution. A solution with pH = 7 is said to be neutral; pH values higher than 7 characterize basic solutions, while acidic solutions have pH values less than 7.

phage (fayj) See bacteriophage.

phagocyte [Gk. *phagein*: to eat + *kystos*: sac] One of two major classes of white blood cells; one of the nonspecific defenses of animals; ingests invading microorganisms by **phagocytosis**.

pharmacogenomics The study of how an individual's genetic makeup affects his or her response to drugs or other agents, with the goal of predicting the effectiveness of different treatment options.

pharming The use of genetically modified animals to produce medically useful products in their milk.

pharynx [Gk. throat] The part of the gut between the mouth and the esophagus.

phenotype (fee' no type) [Gk. *phanein*: to show] The observable properties of an individual resulting from both genetic and environmental factors. (Contrast with genotype.)

phenotypic plasticity See developmental plasticity.

pheromone (feer' o mone) [Gk. *pheros*: carry + *hormon*: excite, arouse] A chemical substance used in communication between organisms of the same species.

phloem (flo' um) [Gk. *phloos*: bark] In vascular plants, the vascular tissue that transports sugars and other solutes from sources to sinks.

phosphate group The functional group —OPO₃H₂.

phosphodiester linkage The connection in a nucleic acid strand, formed by linking two nucleotides.

phospholipid A lipid containing a phosphate group; an important constituent of cellular membranes. (See lipid.)

phospholipid bilayer The basic structural unit of biological membranes; a sheet of phospholipids two molecules thick in which the phospholipids are lined up with their hydrophobic "tails" packed tightly together and their hydrophilic, phosphate-containing "heads" facing outward. Also called lipid bilayer.

phosphorylation Addition of a phosphate group.

photic zone The life zone in lakes and oceans that is penetrated by light and therefore supports photosynthetic organisms.

photoautotroph An organism that obtains energy from light and carbon from carbon dioxide. (Contrast with chemolithotroph, chemoheterotroph, photoheterotroph.)

photoheterotroph An organism that obtains energy from light but must obtain its carbon from organic compounds. (Contrast with chemoautotroph, chemoheterotroph, photoautotroph.)

photomorphogenesis In plants, a process by which physiological and developmental events are controlled by light.

photon (foe' ton) [Gk. *photos*: light] A quantum of visible radiation; a "packet" of light energy.

photoperiodism Control of an organism's physiological or behavioral responses by the length of the day or night (the **photoperiod**).

photophosphorylation Mechanism for ATP formation in chloroplasts in which electron transport is coupled to the transport of hydrogen ions (protons, H^+) across the thylakoid membrane. Compare with chemiosmosis.

photoreceptors (1) In plants, pigments that trigger a physiological response when they absorb a photon. (2) In animals, the sensory receptor cells that sense and respond to light energy. (See cone cells; rod cells.)

photorespiration Light-driven uptake of oxygen and release of carbon dioxide, the carbon being derived from the early reactions of photosynthesis.

photosynthesis (foe tow sin' the sis) [Gk.: creating from light] Metabolic processes carried out by green plants and some microorganisms by which visible light is trapped and the energy used to synthesize compounds such as ATP and glucose.

photosystem [Gk. *phos*: light + *systema*: assembly] A light-harvesting complex in the chloroplast thylakoid composed of pigments and proteins. **Photosystem I** absorbs light at 700 nm, passing electrons to ferredoxin and from there to NADPH. **Photosystem II** absorbs light at 680 nm and passes electrons to the electron transport chain in the chloroplast.

phototropism [Gk. *photos*: light + *trope*: turning] A directed plant growth response to light.

phycobilin Photosynthetic pigment that absorbs red, yellow, orange, and green light and is found in cyanobacteria and some red algae.

phylogeny (fy loj' e nee) [Gk. *phylon*: tribe, race + *genesis*: source] The evolutionary history of a particular group of organisms or their genes. A **phylogenetic tree** is a graphic representation of these lines of evolutionary descent.

physiological survivorship curves See survivorship curves.

physiology (fiz' ee ol' o jee) [Gk. *physis*: natural form] The scientific study of the functions of living organisms and the individual organs, tissues, and cells of which they are composed.

phytoalexins Substances toxic to pathogens, produced by plants in response to fungal or bacterial infection.

phytochrome (fy' tow krome) [Gk. *phyton*: plant + *chroma*: color] A plant pigment regulating a large number of developmental and other phenomena in plants. It has two isomers: P_r , which absorbs red light, and P_{fr} , which absorbs far red light. P_{fr} is the active form.

phytomers In plants, the repeating modules that compose a shoot, each consisting of one or more leaves, attached to the stem at a node; an internode; and one or more axillary buds.

phytoplankton Photosynthetic floating organisms. (See plankton.)

phytoremediation A form of bioremediation that uses plants to clean up environmental pollution.

pigment A substance that absorbs visible light.

piloting A form of navigation in which an animal finds its way by remembering landmarks in its environment.

pineal gland Gland located between the cerebral hemispheres that secretes melatonin.

pinocytosis Endocytosis by a cell of liquid containing dissolved substances.

pistil [L. *pistillum*: pestle] The structure of an angiosperm flower within which the ovules are borne. May consist of a single carpel, or of several carpels fused into a single structure. Usually differentiated into ovary, style, and stigma.

pith In plants, relatively unspecialized tissue found within a cylinder of vascular tissue.

pituitary gland A small gland attached to the base of the brain in vertebrates. Its hormones control the activities of other glands. Also known as the hypophysis.

placenta (pla sen' ta) The organ in female mammals that provides for the nourishment of the fetus and elimination of the fetal waste products.

plankton Aquatic organisms that float in the water column, dependent on currents and wind for movement. Plankton include many protists, some algae, and larval animals. (See also phytoplankton.)

planula (plan' yew la) [L. *planum*: flat] A free-swimming, ciliated larval form typical of the cnidarians.

plaque (plack) [Fr.: a metal plate or coin] (1) A circular clearing in a layer (lawn) of bacteria growing on the surface of a nutrient agar gel. (2) An accumulation of prokaryotic organisms on tooth enamel. Acids produced by these microorganisms cause tooth decay. (3) A region of arterial wall invaded by fibroblasts and fatty deposits.

plasma (plaz' muh) The liquid portion of blood, in which blood cells and other particulates are suspended.

plasma cell An antibody-secreting cell that develops from a B cell; the effector cell of the humoral immune system.

plasma membrane The membrane that surrounds the cell, regulating the entry and exit of molecules and ions. Every cell has a plasma membrane, and it is often called the cell membrane.

plasmid A DNA molecule distinct from the chromosome(s); that is, an extrachromosomal element; found in many bacteria. May replicate independently of the chromosome.

plasmodesmata (singular: plasmodesma) [Gk. *plassein*: to mold + *desmos*: band] Cytoplasmic strands connecting two adjacent plant cells.

plasmogamy The fusion of the cytoplasm of two cells. (Contrast with karyogamy.)

plastid A class of plant cell organelles that includes the chloroplast, which houses biochemical pathways for photosynthesis.

plate tectonics [Gk. *tekton*: builder] The scientific study of the structure and movements of Earth's lithospheric plates, which are the cause of continental drift.

platelet A membrane-bounded body without a nucleus, arising as a fragment of a cell in the bone marrow of mammals. Important to blood-clotting action.

pleiotropy (plee' a tro pee) [Gk. *pleion*: more] The determination of more than one character by a single gene.

pleural membrane [Gk. *pleuras*: rib, side] The membrane lining the outside of the lungs and the walls of the thoracic cavity. Inflammation of these membranes is a condition known as pleurisy.

pluripotent [L. *pluri*: many + *potens*: powerful] Having the ability to form all of the cells in the body. (Contrast with multipotent, totipotent.)

podocytes Cells of Bowman's capsule of the nephron that cover the capillaries of the glomerulus, forming filtration slits.

point mutation A mutation that results from the gain, loss, or substitution of a single nucleotide.

polar A molecule with separate and opposite electric charges at two ends, or poles; the water molecule (H_2O) is the most prevalent example. (Contrast with nonpolar.)

polar body A nonfunctional nucleus produced by meiosis during oogenesis.

polar covalent bond A covalent bond in which the electrons are drawn to one nucleus more than the other, resulting in an unequal distribution of charge.

polar nuclei In angiosperms, the two nuclei in the central cell of the megagametophyte; following fertilization they give rise to the endosperm.

polarity (1) In chemistry, the property of unequal electron sharing in a covalent bond that defines a polar molecule. (2) In development, the difference between one end of an organism or structure and the other.

pollen [L. *pollin*: fine flour] In seed plants, microscopic grains that contain the male gametophyte (microgametophyte) and gamete (microspore).

pollen tube A structure that develops from a pollen grain through which sperm are released into the megagametophyte.

pollination The process of transferring pollen from an anther to the stigma of a pistil in an angiosperm or from a strobilus to an ovule in a gymnosperm.

poly- [Gk. *poly*: many] A prefix denoting multiple entities.

poly A tail A long sequence of adenine nucleotides (50–250) added after transcription to the 3' end of most eukaryotic mRNAs.

polyandry Mating system in which one female mates with multiple males.

polygyny Mating system in which one male mates with multiple females.

polymer [Gk. *poly*: many + *meros*: unit] A large molecule made up of similar or identical subunits called monomers. (Contrast with monomer.)

polymerase chain reaction (PCR) An enzymatic technique for the rapid production of millions of copies of a particular stretch of DNA where only a small amount of the parent molecule is available.

polymorphic (pol' lee mor' fik) [Gk. *poly*: many + *morphe*: form, shape] Coexistence in a population of two or more distinct traits.

polyp (pah' lip) [Gk. *poly*: many + *pous*: foot] In cnidarians, a sessile, asexual life cycle stage.

polypeptide A large molecule made up of many amino acids joined by peptide linkages. Large polypeptides are called proteins.

polyphyletic (pol' lee fih leht' ik) [Gk. *poly*: many + *phylon*: tribe] Pertaining to a group that consists of multiple distantly related organisms, and does not include the common ancestor of the group. (Contrast with monophyletic, paraphyletic.)

polyploid (pol' lee ploid ee) Possessing more than two entire sets of chromosomes.

polyribosome (polysome) A complex consisting of a threadlike molecule of messenger RNA and several (or many) ribosomes. The ribosomes move along the mRNA, synthesizing polypeptide chains as they proceed.

polysaccharide A macromolecule composed of many monosaccharides (simple sugars). Common examples are cellulose and starch.

pons [L. *pons*: bridge] Region of the brainstem anterior to the medulla.

pool The total amount of an element in a given compartment of the biosphere.

population Any group of organisms coexisting at the same time and in the same place and capable of interbreeding with one another.

population bottleneck A period during which only a few individuals of a normally large population survive.

population density The number of individuals in a population per unit of area or volume.

population dynamics The patterns and processes of change in populations.

population genetics The study of genetic variation and its causes within populations.

population size The total number of individuals in a population.

positional information In development, the basis of the spatial sense that induces cells to differentiate as appropriate for their location within the developing organism; often comes in the form of a morphogen gradient.

positive cooperativity Occurs when a molecule can bind several ligands and each one that binds alters the conformation of the molecule so that it can bind the next ligand more easily. The binding of four molecules of O₂ by hemoglobin is an example of positive cooperativity.

positive feedback In regulatory systems, information that amplifies a regulatory response, increasing the deviation of the system from the set point. (Contrast with negative feedback.)

positive regulation A form of gene regulation in which a regulatory macromolecule is needed to turn on the transcription of a structural gene; in its absence, transcription will not occur. (Contrast with negative regulation.)

positive selection Natural selection that acts to establish a trait that enhances survival in a population. (Contrast with purifying selection.)

post- [L. *postere*: behind, following after] Prefix denoting something that comes after.

postabsorptive state State in which no food remains in the gut and thus no nutrients are being absorbed. (Contrast with absorptive state.)

posterior Toward or pertaining to the rear. (Contrast with anterior.)

posterior pituitary A portion of the pituitary gland derived from neural tissue; involved in the storage and release of antidiuretic hormone and oxytocin.

postsynaptic cell The cell that receives information from a neuron at a synapse. (Contrast with presynaptic cell.)

postzygotic isolating mechanisms Barriers to the reproductive process that occur after the union of the nuclei of two gametes. (Contrast with prezygotic isolating mechanisms.)

potential energy Energy not doing work but with the potential to do so, such as the energy stored in chemical bonds. (Contrast with kinetic energy.)

P_r See phytochrome.

pre-mRNA (precursor mRNA) Initial gene transcript before it is modified to produce functional mRNA. Also known as the primary transcript.

Precambrian The first and longest period of geological time, during which life originated.

precapillary sphincter A cuff of smooth muscle that can shut off the blood flow to a capillary bed.

predator An organism that kills and eats other organisms.

pressure flow model An effective model for phloem transport in angiosperms. It holds that sieve element transport is driven by an osmotically generated pressure gradient between source and sink.

pressure potential (Ψ_p) The hydrostatic pressure of an enclosed solution in excess of the surrounding atmospheric pressure.

(Contrast with solute potential, water potential.)

presynaptic cell The neuron that transmits information to another cell at a synapse. (Contrast with postsynaptic cell.)

prey [L. *praeda*: booty] An organism consumed by a predator as an energy source.

prezygotic isolating mechanisms Barriers to the reproductive process that occur before the union of the nuclei of two gametes. (Contrast with postzygotic isolating mechanisms.)

primary active transport Active transport in which ATP is hydrolyzed, yielding the energy required to transport an ion or molecule against its concentration gradient. (Contrast with secondary active transport.)

primary cell wall In plant cells, a structure that forms at the middle lamella after cytokinesis, made up of cellulose microfibrils, hemicelluloses, and pectins. (Contrast with secondary cell wall.)

primary consumer An organism (herbivore) that eats plant tissues.

primary endosymbiosis The engulfment of a cyanobacterium by a larger eukaryotic cell that gave rise to the first photosynthetic eukaryotes with chloroplasts.

primary growth In plants, growth that is characterized by the lengthening of roots and shoots and by the proliferation of new roots and shoots through branching. (Contrast with secondary growth.)

primary immune response The first response of the immune system to an antigen, involving recognition by lymphocytes and the production of effector cells and memory cells. (Contrast with secondary immune response.)

primary meristem Meristem that produces the tissues of the primary plant body.

primary motor cortex See motor cortex

primary oocyte (oh' eh site) [Gk. *oon*: egg + *kytos*: container] The diploid progeny of an oogonium. In many species, a primary oocyte enters prophase of the first meiotic division, then remains in developmental arrest for a long time before resuming meiosis to form a secondary oocyte and a polar body.

primary plant body That part of a plant produced by primary growth. Consists of all the *nonwoody* parts of a plant; many herbaceous plants consist entirely of a primary plant body. (Contrast with secondary plant body.)

primary producer A photosynthetic or chemosynthetic organism that synthesizes complex organic molecules from simple inorganic ones.

primary sex determination Genetic determination of gametic sex, male or female. (Contrast with secondary sex determination.)

primary somatosensory cortex See somatosensory cortex.

primary spermatocyte The diploid progeny of a spermatogonium; undergoes

the first meiotic division to form secondary spermatocytes.

primary structure The specific sequence of amino acids in a protein.

primary succession Succession of ecological communities that begins in an area devoid of life, such as on recently exposed glacial till or lava flows. (Contrast with secondary succession.)

primase An enzyme that catalyzes the synthesis of a primer for DNA replication.

primer Strand of nucleic acid, usually RNA, that is the necessary starting material for the synthesis of a new DNA strand, which is synthesized from the 3' end of the primer.

primordium (plural: primordia) [L. origin] The most rudimentary stage of an organ or other part.

pro- [L.: first, before, favoring] A prefix often used in biology to denote a developmental stage that comes first or an evolutionary form that appeared earlier than another. For example, prokaryote, prophase.

probe A segment of single-stranded nucleic acid used to identify DNA molecules containing the complementary sequence.

procambium Primary meristem that produces the vascular tissue.

procedural memory Memory of motor tasks; these memories cannot be consciously recalled or described. (Contrast with declarative memory.)

processive Pertaining to an enzyme that catalyzes many reactions each time it binds to a substrate, as DNA polymerase does during DNA replication.

products The molecules that result from the completion of a chemical reaction.

progesterone [L. *pro*: favoring + *gestare*: to bear] A female sex hormone that maintains pregnancy.

prokaryotes Unicellular organisms that do not have nuclei or other membrane-enclosed organelles. Includes Bacteria and Archaea. (Contrast with eukaryotes.)

prolactin A hormone released by the anterior pituitary, one of whose functions is the stimulation of milk production in female mammals.

prometaphase The phase of nuclear division that begins with the disintegration of the nuclear envelope.

promoter A DNA sequence to which RNA polymerase binds to initiate transcription.

prop roots Adventitious roots in some monocots that function as supports for the shoot.

prophage (pro' fayj) The noninfectious units that are linked with the chromosomes of the host bacteria and multiply with them but do not cause dissolution of the cell. Prophage can later enter into the lytic phase to complete the virus life cycle.

prophase (pro' phase) The first stage of nuclear division, during which chromosomes

condense from diffuse, threadlike material to discrete, compact bodies.

prostaglandin Any one of a group of specialized lipids with hormone-like functions. It is not clear that they act at any considerable distance from the site of their production.

prostate gland In male humans, surrounds the urethra at its junction with the vas deferens; supplies an acid-neutralizing fluid to the semen.

prosthetic group Any nonprotein portion of an enzyme.

proteases Digestive enzymes that digest proteins.

proteasome In the eukaryotic cytoplasm, a huge protein structure that binds to and digests cellular proteins that have been tagged by ubiquitin.

protein (pro' teen) [Gk. *protos*: first] Long-chain polymer of amino acids with twenty different common side chains. Occurs with its polymer chain extended in fibrous proteins, or coiled into a compact macromolecule in enzymes and other globular proteins. The component amino acids are encoded in the triplets of messenger RNA, and proteins are the products of genes.

protein kinase (kye' nase) An enzyme that catalyzes the addition of a phosphate group from ATP to a target protein.

protein kinase cascade A series of reactions in response to a molecular signal, in which a series of protein kinases activate one another in sequence, amplifying the signal at each step.

proteoglycan A glycoprotein containing a protein core with attached long, linear carbohydrate chains.

proteolysis [protein + Gk. *lysis*: break apart] An enzymatic digestion of a protein or polypeptide.

proteome The complete set of proteins that can be made by an organism. Because of alternative splicing of pre-mRNA, the number of proteins that can be made is usually much larger than the number of protein-coding genes present in the organism's genome.

prothrombin The inactive form of thrombin, an enzyme involved in blood clotting.

protoderm Primary meristem that gives rise to the plant epidermis.

proton (pro' ton) [Gk. *protos*: first, before] (1) A subatomic particle with a single positive charge. The number of protons in the nucleus of an atom determine its element. (2) A hydrogen ion, H⁺.

proton pump An active transport system that uses ATP energy to move hydrogen ions across a membrane, generating an electric potential.

proton-motive force Force generated across a membrane having two components: a chemical potential (difference in proton concentration) plus an electrical potential due to the electrostatic charge on the proton.

protonephridium The excretory organ of flatworms, made up of a tubule and a flame cell.

protoplast The living contents of a plant cell; the plasma membrane and everything contained within it.

provirus Double-stranded DNA made by a virus that is integrated into the host's chromosome and contains promoters that are recognized by the host cell's transcription apparatus.

proximal convoluted tubule The initial segment of a renal tubule, closest to the glomerulus. (Compare with distal convoluted tubule.)

proximal Near the point of attachment or other reference point. (Contrast with distal.)

proximate causes The immediate genetic, physiological, neurological, and developmental mechanisms responsible for a behavior or morphology. (Contrast with ultimate cause.)

pseudocoelomate (soo' do see' low mate) [Gk. *pseudes*: false + *koiloma*: cavity] Having a body cavity, called a pseudocoel, consisting of a fluid-filled space in which many of the internal organs are suspended, but which is enclosed by mesoderm only on its outside.

pseudogene [Gk. *pseudes*: false] A DNA segment that is homologous to a functional gene but is not expressed because of changes to its sequence or changes to its location in the genome.

pseudopod (soo' do pod) [Gk. *pseudes*: false + *podos*: foot] A temporary, soft extension of the cell body that is used in location, attachment to surfaces, or engulfing particles.

pulmonary [L. *pulmo*: lung] Pertaining to the lungs.

pulmonary circuit The portion of the circulatory system by which blood is pumped from the heart to the lungs or gills for oxygenation and back to the heart for distribution. (Contrast with systemic circuit.)

pulmonary valve A one-way valve between the right ventricle of the heart and the pulmonary artery that prevents backflow of blood into the ventricle when it relaxes.

Punnett square Method of predicting the results of a genetic cross by arranging the gametes of each parent at the edges of a square.

pupa (pew' pa) [L. *pupa*: doll, puppet] In certain insects (the Holometabola), the encased developmental stage between the larva and the adult.

pupil The opening in the vertebrate eye through which light passes.

purifying selection The elimination by natural selection of detrimental characters from a population. (Contrast with positive selection.)

purine (pure' een) One of the two types of nitrogenous bases in nucleic acids. Each of the purines—adenine and guanine—pairs with a specific pyrimidine.

Purkinje fibers Specialized heart muscle cells that conduct excitation throughout the ventricular muscle.

pyrimidine (pe rim' a deen) One of the two types of nitrogenous bases in nucleic acids. Each of the pyrimidines—cytosine, thymine, and uracil—pairs with a specific purine.

pyrogen [Gk.: *pyr*, fire;] Molecule that produces a rise in body temperature (fever); may be produced by an invading pathogen or by cells of the immune system in response to infection.

pyruvate The ionized form of pyruvic acid, a three-carbon acid; the end product of glycolysis and the raw material for the citric acid cycle.

pyruvate oxidation Conversion of pyruvate to acetyl CoA and CO₂ that occurs in the mitochondrial matrix in the presence of O₂.

Q

Q₁₀ A value that compares the rate of a biochemical process or reaction over 10°C temperature ranges. A process that is not temperature-sensitive has a Q₁₀ of 1; values of 2 or 3 mean the reaction speeds up as temperature increases.

qualitative Based on observation of an unmeasured quality of a trait, as in brown vs. blue.

quantitative Based on numerical values obtained by measurement, as in quantitative data.

quantitative trait loci A set of genes determining a complex character (trait) that exhibits quantitative variation (variation in amount rather than in kind).

quaternary structure The specific three-dimensional arrangement of protein subunits. Contrast with primary, secondary, tertiary structure.

quorum sensing The use of chemical communication signals to trigger density-linked activities such as biofilm formation in prokaryotes.

R

R group The distinguishing group of atoms of a particular amino acid; also known as a side chain.

r-strategist A species whose life history strategy allows for a high intrinsic rate of population increase (*r*). (Contrast with *K*-strategist.)

radial symmetry The condition in which any two halves of a body are mirror images of each other, providing the cut passes through the center; a cylinder cut lengthwise down its center displays this form of symmetry.

radiation The transfer of heat from warmer objects to cooler ones via the exchange of infrared radiation. *See also* electromagnetic radiation; evolutionary radiation.

radicle An embryonic root.

radioisotope A radioactive isotope of an element. Examples are carbon-14 (¹⁴C) and hydrogen-3, or tritium (³H).

radiometric dating A method for determining the age of objects such as fossils and rocks based on the decay rates of radioactive isotopes.

rapid eye movement sleep *See* REM sleep.

reactant A chemical substance that enters into a chemical reaction with another substance.

reaction center A group of electron transfer proteins that receive energy from light-absorbing pigments and convert it to chemical energy by redox reactions.

realized niche A species' niche as defined by its interactions with other species. (Contrast with fundamental niche.)

receptive field The area of visual space that activates a particular cell in the visual system.

receptor *See* receptor protein, sensory receptor cell.

receptor potential The change in the resting potential of a sensory cell when it is stimulated.

receptor protein A protein that can bind to a specific molecule, or detect a specific stimulus, within the cell or in the cell's external environment.

receptor-mediated endocytosis Endocytosis initiated by macromolecular binding to a specific membrane receptor.

recessive In genetics, an allele that does not determine phenotype in the presence of a dominant allele. (Contrast with dominance.)

reciprocal crosses A pair of matings in one of which a female of genotype A mates with a male of genotype B and in the other of which a female of genotype B mates with a male of genotype A.

recognition sequence *See* restriction site.

recombinant Pertaining to an individual, meiotic product, or chromosome in which genetic materials originally present in two individuals end up in the same haploid complement of genes.

recombinant DNA A DNA molecule made in the laboratory that is derived from two or more genetic sources.

recombinant frequency The proportion of offspring of a genetic cross that have phenotypes different from the parental phenotypes due to crossing over between linked genes during gamete formation.

recombination frequency The proportion of offspring of a genetic cross that have phenotypes different from the parental phenotypes due to crossing over between linked genes during gamete formation.

reconciliation ecology The practice of making exploited lands more biodiversity-friendly. Compare with restoration ecology.

rectum The terminal portion of the gut, ending at the anus.

redox reaction A chemical reaction in which one reactant is oxidized (loses electrons) and the other is reduced (gains electrons). Short for reduction–oxidation reaction.

reduction Gain of electrons by a chemical reactant. (Contrast with oxidation.)

refractory period The time interval after an action potential during which another action potential cannot be elicited from an excitable membrane.

regeneration The development of a complete individual from a fragment of an organism.

regulative development A pattern of animal embryonic development in which the fates of the first blastomeres are not absolutely fixed. (Contrast with mosaic development.)

regulatory gene A gene that codes for a protein (or RNA) that in turn controls the expression of another gene.

regulatory sequence A DNA sequence to which the protein product of a regulatory gene binds.

regulatory system A system that uses feedback information to maintain a physiological function or parameter at an optimal level. (Contrast with controlled system.)

regulatory T cells (Treg) The class of T cells that mediates tolerance to self antigens.

reinforcement The evolution of enhanced reproductive isolation between populations due to natural selection for greater isolation.

Reissner's membrane *See* tectonic membrane.

releaser Sensory stimulus that triggers performance of a stereotyped behavior pattern.

REM (rapid-eye-movement) sleep A sleep state characterized by vivid dreams, skeletal muscle relaxation, and rapid eye movements. (Contrast with non-REM sleep.)

renal [L. *renes*: kidneys] Relating to the kidneys.

renal tubule A structural unit of the kidney that collects filtrate from the blood, reabsorbs specific ions, nutrients, and water and returns them to the blood, and concentrates excess ions and waste products such as urea for excretion from the body.

renin An enzyme released from the kidneys in response to a drop in the glomerular filtration rate. Together with angiotensin converting enzyme, converts an inactive protein in the blood into angiotensin.

replication The duplication of genetic material.

replication complex The close association of several proteins operating in the replication of DNA.

replication fork A point at which a DNA molecule is replicating. The fork forms by the unwinding of the parent molecule.

replicon A region of DNA replicated from a single origin of replication.

reporter gene A genetic marker included in recombinant DNA to indicate the presence of the recombinant DNA in a host cell.

repressor A protein encoded by a regulatory gene that can bind to a promoter and prevent transcription of the associated gene. (Contrast with activator.)

reproductive isolation Condition in which two divergent populations are no longer exchanging genes. Can lead to speciation.

rescue effect The process by which individuals moving between subpopulations of a metapopulation may prevent declining subpopulations from becoming extinct.

residence time The length of time a chemical element (e.g., carbon or nitrogen) remains in a given compartment of the ecosystem (e.g., in an organic body, in soil, in the atmosphere).

residual volume (RV) In tidal ventilation, the dead space that remains in the lungs at the end of exhalation.

resistance (R) genes Plant genes that confer resistance to specific strains of pathogens.

resource Something in the environment required by an organism for its maintenance and growth that is consumed in the process of being used.

resource partitioning A situation in which selection pressures resulting from interspecific competition cause changes in the ways in which the competing species use the limiting resource, thereby allowing them to coexist.

respiration (res pi ra' shun) [L. *spirare*: to breathe] (1) Cellular respiration. (2) Breathing.

respiratory chain The terminal reactions of cellular respiration, in which electrons are passed from NAD or FAD, through a series of intermediate carriers, to molecular oxygen, with the concomitant production of ATP.

respiratory gases Oxygen (O₂) and carbon dioxide (CO₂); the gases that an animal must exchange between its internal body fluids and the outside medium (air or water).

resting potential The membrane potential of a living cell at rest. In cells at rest, the interior is negative to the exterior. (Contrast with action potential.)

restoration ecology The science and practice of restoring damaged or degraded ecosystems.

restriction enzyme Any of a type of enzyme that cleaves double-stranded DNA at specific sites; extensively used in recombinant DNA technology. Also called a restriction endonuclease.

restriction fragment length polymorphism See RFLP.

restriction point (R) The specific time during G1 of the cell cycle at which the cell becomes committed to undergo the rest of the cell cycle.

restriction site A specific DNA base sequence that is recognized and acted on by a restriction endonuclease.

reticular activating system A central region of the vertebrate brainstem that includes complex fiber tracts conveying neural signals between the forebrain and the spinal cord, with collateral fibers to a variety of nuclei that are involved in autonomic functions, including arousal from sleep.

reticulum One of the four chambers of the ruminant stomach. Along with the rumen, where food is partially digested with the assistance of gut bacteria.

retina (rett' in uh) [L. *rete*: net] The light-sensitive layer of cells in the vertebrate or cephalopod eye.

retrotransposons Mobile genetic elements that are reverse transcribed into RNA as part of their transfer mechanism. (Contrast with DNA transposons.)

retrovirus An RNA virus that contains reverse transcriptase. Its RNA serves as a template for cDNA production, and the cDNA is integrated into a chromosome of the host cell.

reverse genetics Method of genetic analysis in which a phenotype is first related to a DNA variation, then the protein involved is identified.

reverse transcriptase An enzyme that catalyzes the production of DNA (cDNA), using RNA as a template; essential to the reproduction of retroviruses.

reversion mutation A second- or third-round mutation that reverts the DNA to its original sequence or to a new sequence that results in a non-mutant phenotype.

RFLP Restriction fragment length polymorphism, the coexistence of two or more patterns of restriction fragments resulting from underlying differences in DNA sequence.

rhizoids (rye' zoids) [Gk. root] Hairlike extensions of cells in mosses, liverworts, and a few vascular plants that serve the same function as roots and root hairs in vascular plants. The term is also applied to branched, rootlike extensions of some fungi and algae.

rhizome (rye' zome) An underground stem (as opposed to a root) that runs horizontally beneath the ground.

rhodopsin A vertebrate visual pigment involved in transducing photons of light into changes in the membrane potential of certain photoreceptor cells.

ribonucleic acid See RNA.

ribose A five-carbon sugar in nucleotides and RNA.

ribosomal RNA (rRNA) Several species of RNA that are incorporated into the ribosome. Involved in peptide bond formation.

ribosome A small particle in the cell that is the site of protein synthesis.

ribozyme An RNA molecule with catalytic activity.

ribulose biphosphate carboxylase/oxygenase See rubisco.

risk cost The increased chance of being injured or killed as a result of performing a behavior, compared to resting.

RNA (ribonucleic acid) An often single-stranded nucleic acid whose nucleotides use ribose rather than deoxyribose and in which the base uracil replaces thymine found in DNA. Serves as genome for some viruses. (See ribosomal RNA, transfer RNA, messenger RNA, and ribozyme.)

RNA interference (RNAi) A mechanism for reducing mRNA translation whereby a double-stranded RNA, made by the cell or synthetically, is processed into a small, single-stranded RNA, whose binding to a target mRNA results in the latter's breakdown.

RNA polymerase An enzyme that catalyzes the formation of RNA from a DNA template.

RNA splicing The last stage of RNA processing in eukaryotes, in which the transcripts of introns are excised through the action of small nuclear ribonucleoprotein particles (snRNP).

rod cells Light-sensitive cells in the vertebrate retina; these sensory receptor cells are sensitive in extremely dim light and are responsible for dim light, black and white vision.

root The organ responsible for anchoring the plant in the soil, absorbing water and minerals, and producing certain hormones. Some roots are storage organs.

root apical meristem Undifferentiated tissue at the apex of the root that gives rise to the organs of the root.

root cap A thimble-shaped mass of cells, produced by the root apical meristem, that protects the meristem; the organ that perceives the gravitational stimulus in root gravitropism.

root hair A long, thin process from a root epidermal cell that absorbs water and minerals from the soil solution.

root system The organ system that anchors a plant in place, absorbs water and dissolved minerals, and may store products of photosynthesis from the shoot system.

rough endoplasmic reticulum (RER) The portion of the endoplasmic reticulum whose outer surface has attached ribosomes. (Contrast with smooth endoplasmic reticulum.)

round window A flexible membrane at the end of the lower canal of the cochlea in the human ear. (See also oval window.)

rRNA See ribosomal RNA.

rubisco Contraction of ribulose biphosphate carboxylase/oxygenase, the enzyme that combines carbon dioxide or oxygen with ribulose biphosphate to catalyze the first step of photosynthetic carbon fixation or photorespiration, respectively.

rumen One of the four chambers of the ruminant stomach. Along with the reticulum, where food is partially digested with the assistance of gut bacteria.

ruminant Herbivorous, cud-chewing mammals such as cows or sheep, characterized by a stomach that consists of four compartments: the rumen, reticulum, omasum, and abomasum.

S

S phase In the cell cycle, the stage of interphase during which DNA is replicated. (Contrast with G1 phase, G2 phase, M phase.)

salt glands Glands on the leaves of some halophytic plants that secrete salt, thereby ridding the plants of excess salt.

saltatory conduction [L. *saltare*: to jump] The rapid conduction of action potentials in myelinated axons; so called because action potentials appear to “jump” between nodes of Ranvier along the axon.

saprobe [Gk. *sapros*: rotten] An organism (usually a bacterium or fungus) that obtains its carbon and energy by absorbing nutrients from dead organic matter.

sarcomere (sark' o meer) [Gk. *sark*: flesh + *meros*: unit] The contractile unit of a skeletal muscle.

sarcoplasm The cytoplasm of a muscle cell.

sarcoplasmic reticulum The endoplasmic reticulum of a muscle cell.

saturated fatty acid A fatty acid in which all the bonds between carbon atoms in the hydrocarbon chain are single bonds—that is, all the bonds are saturated with hydrogen atoms. (Contrast with unsaturated fatty acid.)

Schwann cell A type of glial cell that myelinates axons in the peripheral nervous system.

scientific method A means of gaining knowledge about the natural world by making observations, posing hypotheses, and conducting experiments to test those hypotheses.

scion In horticulture, the bud or stem from one plant that is grafted to a root or root-bearing stem of another plant (the stock).

scleireid One of the principle types of cells in sclerenchyma.

sclerenchyma (skler eng' kyma) [Gk. *skleros*: hard + *kymus*: juice] A plant tissue composed of cells with heavily thickened cell walls. The cells are dead at functional maturity. The principal types of sclerenchyma cells are fibers and sclereids.

scrotum In most mammals, a pouch outside the body cavity that contains the testes.

second filial generation See F₂.

second law of thermodynamics The principle that when energy is converted from one form to another, some of that energy becomes unavailable for doing work.

second messenger A compound, such as cAMP, that is released within a target cell

after a hormone (the first messenger) has bound to a surface receptor on a cell; the second messenger triggers further reactions within the cell.

second polar body In oogenesis, the daughter cell of the second meiotic division that subsequently degenerates. (See also ootid.)

secondary active transport A form of active transport that does not use ATP as an energy source; rather, transport is coupled to ion diffusion down a concentration gradient established by primary active transport.

secondary cell wall A thick, cellulosic structure internal to the primary cell wall formed in some plant cells after cell expansion stops (Contrast with primary cell wall.)

secondary consumer An organism that eats primary consumers. (Contrast with primary consumer.)

secondary endosymbiosis The engulfment of a photosynthetic eukaryote by another eukaryotic cell that gave rise to certain groups of photosynthetic eukaryotes (e.g., euglenids).

secondary growth In plants, growth that contributes to an increase in girth. (Contrast with primary growth.)

secondary immune response A rapid and intense response to a second or subsequent exposure to an antigen, initiated by memory cells. (Contrast with primary immune response.)

secondary lysosome Membrane-enclosed organelle formed by the fusion of a primary lysosome with a phagosome, in which macromolecules taken up by phagocytosis are hydrolyzed into their monomers. (Contrast with lysosome.)

secondary metabolite A compound synthesized by a plant that is not needed for basic cellular metabolism. Typically has an antiherbivore or antiparasite function.

secondary oocyte In oogenesis, the daughter cell of the first meiotic division that receives almost all the cytoplasm. (See also first polar body.)

secondary plant body That part of a plant produced by secondary growth; consists of woody tissues. (Contrast with primary plant body.)

secondary sex determination Formation of secondary sexual characteristics (i.e., those other than gonads), such as external sex organs and body hair. (Contrast with primary sex determination.)

secondary spermatocyte One of the products of the first meiotic division of a primary spermatocyte.

secondary structure Of a protein, localized regularities of structure, such as the α helix and the β pleated sheet. (Contrast with primary, tertiary, quaternary structure.)

secondary succession Succession of ecological communities after a disturbance that did not eliminate all the organisms

originally living on the site. (Contrast with primary succession.)

secretin (si kreet' in) A peptide hormone secreted by the upper region of the small intestine when acidic chyme is present. Stimulates the pancreatic duct to secrete bicarbonate ions.

sedimentary rock Rock formed by the accumulation of sediment grains on the bottom of a body of water. Often contain stratified fossils that allow geologists and biologist to date evolutionary events relative to each other.

seed A fertilized, ripened ovule of a gymnosperm or angiosperm. Consists of the embryo, nutritive tissue, and a seed coat.

seedling A plant that has just completed the process of germination.

segment polarity genes In *Drosophila* (fruit fly) development, segmentation genes that determine the boundaries and anterior–posterior organization of individual segments. Part of a developmental cascade that includes maternal effect genes, gap genes, pair rule genes, and Hox genes.

segmentation Division of an animal body into segments.

segmentation genes Genes that determine the number and polarity of body segments.

segregation In genetics, the separation of alleles, or of homologous chromosomes, from each other during meiosis so that each of the haploid daughter nuclei produced contains one or the other member of the pair found in the diploid parent cell, but never both. This principle was articulated by Mendel as his first law.

selectable marker A gene, such as one encoding resistance to an antibiotic, that can be used to identify (select) cells that contain recombinant DNA from among a large population of untransformed cells.

selective permeability Allowing certain substances to pass through while other substances are excluded; a characteristic of membranes.

self-incompatibility In plants, the possession of mechanisms that prevent self-fertilization.

semelparous [L. *semel*: once + *pario*: to beget] Reproducing only once in a lifetime. (Contrast with iteroparous.)

semen (see' men) [L. *semin*: seed] The thick, whitish liquid produced by the male reproductive system in mammals, containing the sperm.

semicircular canals Three canals in the human inner ear that form part of the vestibular system.

semiconservative replication The way in which DNA is synthesized. Each of the two partner strands in a double helix acts as a template for a new partner strand. Hence, after replication, each double helix consists of one old and one new strand.

seminiferous tubules The tubules within the testes within which sperm production occurs.

senescence [L. *senescere*: to grow old] Aging; deteriorative changes with aging; the increased probability of dying with increasing age.

sensitive period The life stage during which some particular type of learning must take place, or during which it occurs much more easily than at other times. Typical of song learning among birds. Also known as the critical period.

sensory receptor cell Cell that is responsive to a particular type of physical or chemical stimulation. Sometimes referred to as a sensor.

sensory system A set of organs and tissues for detecting a stimulus; consists of sensory cells, the associated structures, and the neural networks that process the information.

sensory transduction The transformation of environmental stimuli or information into neural signals.

sepal (see' pul) [L. *sepalum*: covering] One of the outermost structures of the flower, usually protective in function and enclosing the rest of the flower in the bud stage.

septate [L. wall] Divided, as by walls or partitions.

septum (plural: septa) (1) A partition or cross-wall appearing in the hyphae of some fungi. (2) The bony structure dividing the nasal passages.

sequence alignment A method of identifying homologous positions in DNA or amino acid sequences by pinpointing the locations of deletions and insertions that have occurred since two (or more) organisms diverged from a common ancestor.

Sertoli cells Cells in the seminiferous tubules of the testes that nurture the developing sperm.

sessile (sess' ul) [L. *sedere*: to sit] Permanently attached; not able to move from one place to another. (Contrast with motile.)

set point In a regulatory system, the threshold sensitivity to the feedback stimulus.

sex chromosome In organisms with a chromosomal mechanism of sex determination, one of the chromosomes involved in sex determination (in humans and many other animals, these are the X and Y chromosomes).

sex-linked inheritance Pattern of inheritance characteristic of genes located on the sex chromosomes of organisms having a chromosomal mechanism for sex determination.

sex pilus A thin connection between two bacteria through which genetic material passes during conjugation.

sexual reproduction Reproduction involving the union of gametes.

sexual selection Selection by one sex of characteristics in individuals of the opposite sex. Also, the favoring of characteristics in

one sex as a result of competition among individuals of that sex for mates.

shared derived trait See synapomorphy.

shoot apical meristem Undifferentiated tissue at the apex of the shoot that gives rise to the organs of the shoot.

shoot system In plants, the organ system consisting of the leaves, stem(s), and flowers.

short-day plant (SDP) A plant that flowers when nights are longer than a critical length specific for that plant's species. (Compare to long-day plant.)

short tandem repeats (STRs) Short (1–5 base pairs), moderately repetitive sequences of DNA. The number of copies of an STR at a particular location varies between individuals and is inherited.

side chain See R group.

sieve tube element The characteristic cell of the phloem in angiosperms, which contains cytoplasm but relatively few organelles, and whose end walls (**sieve plates**) contain pores that form connections with neighboring cells.

sigma factor In prokaryotes, a protein that binds to RNA polymerase, allowing the complex to bind to and stimulate the transcription of a specific class of genes (e.g., those involved in sporulation).

signal sequence The sequence within a protein that directs the protein to a particular organelle.

signal transduction pathway The series of biochemical steps whereby a stimulus to a cell (such as a hormone or neurotransmitter binding to a receptor) is translated into a response of the cell.

silencer A gene sequence binding transcription factors that repress transcription. (Contrast with promoter.)

silent mutation A change in a gene's sequence that has no effect on the amino acid sequence of a protein either because it occurs in noncoding DNA or because it does not change the amino acid specified by the corresponding codon. (Contrast with frame-shift mutation, missense mutation, nonsense mutation.)

silent substitution See synonymous substitution.

similarity matrix A matrix used to compare the degree of divergence among pairs of objects. For molecular sequences, constructed by summing the number or percentage of nucleotides or amino acids that are identical in each pair of sequences.

simple diffusion Diffusion that does not involve a direct input of energy or assistance by carrier proteins.

single nucleotide polymorphisms (SNPs) Inherited variations in a single nucleotide base in DNA that differ between individuals.

single-strand binding protein In DNA replication, a protein that binds to single strands of DNA after they have been separated from each other, keeping the two strands separate for replication.

sink In plants, any organ that imports the products of photosynthesis, such as roots, developing fruits, and immature leaves. (Contrast with source.)

sinoatrial node (sigh' no ay' tree al) [L. *sinus*: curve + *atrium*: chamber] The pacemaker of the mammalian heart.

siRNAs (small interfering RNAs) Short, double-stranded RNA molecules used in RNA interference.

sister chromatid Each of a pair of newly replicated chromatids.

sister species Two species that are each other's closest relatives.

skeletal muscle A type of muscle tissue characterized by multinucleated cells containing highly ordered arrangements of actin and myosin microfilaments. Also called striated muscle. (Contrast with cardiac muscle, smooth muscle.)

skeletal systems Organ systems that provide rigid supports—**skeletons**—against which muscles can pull to create directed movements. See also endoskeleton, exoskeleton.

sliding DNA clamp Protein complex that keeps DNA polymerase bound to DNA during replication.

sliding filament model Mechanism of muscle contraction based on the formation and breaking of crossbridges between actin and myosin filaments, causing the filaments to slide together.

slow-twitch fibers Skeletal muscle fibers specialized for sustained aerobic work; contain myoglobin and abundant mitochondria, and are well-supplied with blood vessels. Also called oxidative or red muscle fibers. (Compare to fast-twitch fibers.)

slow-wave sleep See non-REM sleep.

small interfering RNAs See siRNAs.

small intestine The portion of the gut between the stomach and the colon; consists of the duodenum, the jejunum, and the ileum.

small nuclear ribonucleoprotein particle (snRNP) A complex of an enzyme and a small nuclear RNA molecule, functioning in RNA splicing.

smooth endoplasmic reticulum (SER) Portion of the endoplasmic reticulum that lacks ribosomes and has a tubular appearance. (Contrast with rough endoplasmic reticulum.)

smooth muscle Muscle tissue consisting of sheets of mononucleated cells innervated by the autonomic nervous system. (Contrast with cardiac muscle, skeletal muscle.)

sodium–potassium (Na⁺–K⁺) pump Antiporter responsible for primary active transport; it pumps sodium ions out of the cell and potassium ions into the cell, both against their concentration gradients. Also called a sodium–potassium ATPase.

soil horizon See horizons.

soil solution The aqueous portion of soil, from which plants take up dissolved mineral nutrients.

solute A substance that is dissolved in a liquid (solvent) to form a solution.

solute potential (Ψ_s) A property of any solution, resulting from its solute contents; it may be zero or have a negative value. The more negative the solute potential, the greater the tendency of the solution to take up water through a differentially permeable membrane. (Contrast with pressure potential, water potential.)

solution A liquid (the solvent) and its dissolved solutes.

solvent Liquid in which a substance (solute) is dissolved to form a solution.

somatic cell [Gk. *soma*: body] All the cells of the body that are not specialized for reproduction. (Contrast with germ cell.)

somatic mutation Permanent genetic change in a somatic cell (as opposed to a germ cell, the egg or sperm). These mutations affect the individual only; they are not passed on to offspring. (Contrast with germ line mutation.)

somatosensory cortex An area of the parietal lobe that receives touch and pressure information from mechanoreceptors throughout the body; neurons in this area are arranged according to the parts of the body with which they communicate.

somatostatin Peptide hormone made in the hypothalamus that inhibits the release of other hormones from the pituitary and intestine.

somite (so' might) One of the segments into which an embryo becomes divided longitudinally, leading to the eventual segmentation of the animal as illustrated by the spinal column, ribs, and associated muscles.

source In plants, any organ that exports the products of photosynthesis in excess of its own needs, such as a mature leaf or storage organ. (Contrast with sink.)

spatial summation In the production or inhibition of action potentials in a postsynaptic cell, the interaction of depolarizations and hyperpolarizations produced at different sites on the postsynaptic cell. (Contrast with temporal summation.)

spawning See external fertilization.

speciation (spee' see ay' shun) The process of splitting one population into two populations that are reproductively isolated from one another.

species (spee' sees) [L. *kind*] The base unit of taxonomic classification, consisting of an ancestor-descendant group of populations of evolutionarily closely related, similar organisms. The more narrowly defined "biological species" consists of individuals capable of interbreeding with each other but not with members of other species.

species composition The particular mix of species a community contains and the abundances of those species.

species evenness A measure of species diversity that reflects the distribution of the species' abundances in a community.

species richness The total number of species living in a region.

species-area relationship The relationship between the size of an area and the numbers of species it supports.

specific defenses Defensive reactions of the vertebrate immune system that are based on the reaction of an antibody to a specific antigen. (Contrast with nonspecific defenses.)

specific heat The amount of energy that must be absorbed by a gram of a substance to raise its temperature by one degree centigrade. By convention, water is assigned a specific heat of one.

sperm [Gk. *sperma*: seed] The male gamete.

spermatid One of the products of the second meiotic division of a primary spermatocyte; four haploid spermatids, which remain connected by cytoplasmic bridges, are produced for each primary spermatocyte that enters meiosis.

spermatogenesis (spur mat' oh jen' e sis) [Gk. *sperma*: seed + *genesis*: source] Gametogenesis leading to the production of sperm.

spermatogonia In animals, the diploid progeny of a germ cell in males.

spherical symmetry The simplest form of symmetry, in which body parts radiate out from a central point such that an infinite number of planes passing through that central point can divide the organism into similar halves.

sphincter (sfin' ter) [Gk. *sphinkter*: something that binds tightly] A ring of muscle that can close an orifice, for example, at the anus.

spicule [L. *arrowhead*] A hard, calcareous skeletal element typical of sponges.

spinal cord Along with the brain, part of the central nervous system; transmits information between the body and the brain and mediates simple reflexes.

spinal reflex The conversion of afferent to efferent information in the spinal cord without participation of the brain.

spindle apparatus [O.E. *spindle*, a short stick with tapered ends] Array of microtubules emanating from both poles of a dividing cell during mitosis and playing a role in the movement of chromosomes at nuclear division.

spleen Organ that serves as a reservoir for venous blood and eliminates old, damaged red blood cells from the circulation.

spliceosome RNA-protein complex that splices out introns from eukaryotic pre-mRNAs.

splicing See RNA splicing.

spontaneous mutation A genetic change caused by internal cellular mechanisms, such as an error in DNA replication. (Contrast with induced mutation.)

sporangiophore A stalked reproductive structure produced by zygosporic fungi that extends from a hypha and bears one or many sporangia.

sporangium (spor an' gee um) (plural: sporangia) [Gk. *spora*: seed + *angeion*: vessel or reservoir] In plants and fungi, any specialized structure within which one or more spores are formed.

spore [Gk. *spora*: seed] (1) Any asexual reproductive cell capable of developing into an adult organism without gametic fusion. In plants, haploid spores develop into gametophytes, diploid spores into sporophytes. (2) In prokaryotes, a resistant cell capable of surviving unfavorable periods.

sporocyte Specialized cells of the diploid sporophyte that will divide by meiosis to produce four haploid spores. Germination of these spores produces the haploid gametophyte.

sporophyte (spor' o fyte) [Gk. *spora*: seed + *phyton*: plant] In plants and protists with alternation of generations, the diploid phase that produces the spores. (Contrast with gametophyte.)

stabilizing selection Selection against the extreme phenotypes in a population, so that the intermediate types are favored. (Contrast with disruptive selection.)

stamen (stay' men) [L. *stamen*: thread] A male (pollen-producing) unit of a flower, usually composed of an anther, which bears the pollen, and a filament, which is a stalk supporting the anther.

starch [O.E. *stearc*: stiff] A polymer of glucose; used by plants to store energy.

Starling's forces The two opposing forces responsible for water movement across capillary walls: blood pressure, which squeezes water and small solutes out of the capillaries, and osmotic pressure, which pulls water back into the capillaries.

start codon The mRNA triplet (AUG) that acts as a signal for the beginning of translation at the ribosome. (Contrast with stop codon.)

stele (steel) [Gk.: pillar] The central cylinder of vascular tissue in a plant stem.

stem cell In animals, an undifferentiated cell that is capable of continuous proliferation. A stem cell generates more stem cells and a large clone of differentiated progeny cells. (See also embryonic stem cell.)

stem In plants, the organ that holds leaves and/or flowers and transports and distributes materials among the other organs of the plant.

stereocilia Fingerlike extensions of hair cell membranes whose bending initiates sound perception. (See hair cell.)

steroid Any of a family of lipids whose multiple rings share carbons. The steroid

cholesterol is an important constituent of membranes and is the base of steroid hormones such as testosterone.

sticky ends On a piece of two-stranded DNA, short, complementary, one-stranded regions produced by the action of a restriction endonuclease. Sticky ends facilitate the joining of segments of DNA from different sources.

stigma [L. *stigma*: mark, brand] The part of the pistil at the apex of the style that is receptive to pollen, and on which pollen germinates.

stimulus [L. *stimulare*: to goad] Something causing a response; something in the environment detected by a receptor.

stock In horticulture, the root or root-bearing stem to which a bud or piece of stem from another plant (the scion) is grafted.

stoma (plural: stomata) [Gk. *stoma*: mouth, opening] Small opening in the plant epidermis that permits gas exchange; bounded by a pair of guard cells whose osmotic status regulates the size of the opening.

stomach An organ that physically (and sometimes enzymatically) breaks down food, preparing it for digestion in the midgut.

stomatal crypt In plants, a sunken cavity below the leaf surface in which a stoma is sheltered from the drying effects of air currents.

stop codon Any of the three mRNA codons that signal the end of protein translation at the ribosome: UAG, UGA, UAA.

stratosphere The upper part of Earth's atmosphere, above the troposphere; extends from approximately 18 kilometers upward to approximately 50 kilometers above Earth's surface.

stratum (plural strata) [L. *stratos*: layer] A layer of sedimentary rock laid down at a particular time in the past.

stretch receptor A modified muscle cell embedded in the connective tissue of a muscle that acts as a mechanoreceptor in response to stretching of that muscle.

striated muscle See skeletal muscle.

strigolactones Signaling molecules produced by plant roots that attract the hyphae of mycorrhizal fungi.

strobilus (plural: strobili) One of several conelike structures in various groups of plants (including club mosses, horsetails, and conifers) associated with the production and dispersal of reproductive products.

stroke An embolism in an artery in the brain that causes the cells fed by that artery to die. The specific damage, such as memory loss, speech impairment, or paralysis, depends on the location of the blocked artery.

stroma The fluid contents of an organelle such as a chloroplast or mitochondrion.

structural gene A gene that encodes the primary structure of a protein not involved in the regulation of gene expression.

structural isomers Molecules made up of the same kinds and numbers of atoms, in which the atoms are bonded differently.

structural motif A three-dimensional structural element that is part of a larger molecule. For example, there are four common motifs in DNA-binding proteins: helix-turn-helix, zinc finger, leucine zipper, and helix-loop-helix.

style [Gk. *stèle*: pillar or column] In the angiosperm flower, a column of tissue extending from the tip of the ovary, and bearing the stigma or receptive surface for pollen at its apex.

sub- [L. *under*] A prefix used to designate a structure that lies beneath another or is less than another. For example, subcutaneous (beneath the skin); subspecies

subduction In plate tectonics, the movement of one lithospheric plate under another.

suberin A waxlike lipid that is a barrier to water and solute movement across the Casparian strip of the endodermis.

submucosa (sub mew koe' sah) The tissue layer just under the epithelial lining of the lumen of the digestive tract.

subsoil The soil horizon lying below the topsoil and above the parent rock (bedrock); the zone of infiltration and accumulation of materials leached from the topsoil. Also called the B horizon.

substrate (sub' strayte) (1) The molecule or molecules on which an enzyme exerts catalytic action. (2) The base material on which a sessile organism lives.

succession The gradual, sequential series of changes in the species composition of an ecological community following a disturbance. See also cyclical succession, directional selection, heterotrophic succession.

succulence In plants, possession of fleshy, water-storing leaves or stems; an adaptation to dry environments.

sulcus (sul' kus; plural sulci) [Gk.: plowed furrow] See convolutions.

superficial cleavage A variation of incomplete cleavage in which cycles of mitosis occur without cell division, producing a syncytium (a single cell with many nuclei).

suprachiasmatic nuclei (SCN) In mammals, two clusters of neurons just above the optic chiasm that act as the master circadian clock.

surface area-to-volume ratio For any cell, organism, or geometrical solid, the ratio of surface area to volume; this is an important factor in setting an upper limit on the size a cell or organism can attain.

surface tension The attractive intermolecular forces at the surface of liquid; an especially important property of water.

surfactant A substance that decreases the surface tension of a liquid. Lung surfactant, secreted by cells of the alveoli, is mostly

phospholipid and decreases the amount of work necessary to inflate the lungs.

survivorship The fraction of individuals that survive from birth to a given life stage or age.

survivorship curves Graphic plot of ages at death of a hypothetical cohort, usually of 1,000 individuals, by plotting the numbers of individuals expected to survive to reach each age category. There are three general shapes. Ecological survivorship is linear: individuals face a constant risk of mortality regardless of their age. Physiological survivorship curves are concave: high survivorship through adulthood with steep declines late in life. Maturation survivorship curves are convex, with high mortality early in life but higher survivorship once individuals reach maturity.

suspensor In the embryos of seed plants, the stalk of cells that pushes the embryo into the endosperm and is a source of nutrient transport to the embryo.

sustainable Pertaining to the use and management of ecosystems in such a way that humans benefit over the long term from specific ecosystem goods and services without compromising others.

symbiosis (sim' bee oh' sis) [Gk. *sym*: together + *bios*: living] The living together of two or more species in a prolonged and intimate relationship.

symmetry Pertaining to an attribute of an animal body in which at least one plane can divide the body into similar, mirror-image halves. (See bilateral symmetry, radial symmetry.)

sympathetic nervous system The division of the autonomic nervous system that works in opposition to the parasympathetic nervous system. (Contrast with parasympathetic nervous system.)

sympatric speciation (sim pat' rik) [Gk. *sym*: same + *patria*: homeland] Speciation due to reproductive isolation without any physical separation of the subpopulation. (Contrast with allopatric speciation.)

symplast The continuous meshwork of the interiors of living cells in the plant body, resulting from the presence of plasmodesmata. (Contrast with apoplast.)

symporter A membrane transport protein that carries two substances in the same direction. (Contrast with antiporter, uniporter.)

synapomorphy A trait that arose in the ancestor of a phylogenetic group and is present (sometimes in modified form) in all of its members, thus helping to delimit and identify that group. Also called a shared derived trait.

synapse (sin' aps) [Gk. *syn*: together + *haptein*: to fasten] A specialized type of junction where a neuron meets its target cell (which can be another neuron or some other type of cell) and information in the form of neurotransmitter molecules is exchanged across a synaptic cleft.

synapsis (sin ap' sis) The highly specific parallel alignment (pairing) of homologous chromosomes during the first division of meiosis.

synaptic cleft The space between the presynaptic cell and the postsynaptic cell in a chemical synapse.

synergids [Gk. *syn*: together + *ergos*: work] In angiosperms, the two cells accompanying the egg cell at one end of the megagametophyte.

syngamy See fertilization.

synonymous (silent) substitution A change of one nucleotide in a sequence to another when that change does not affect the amino acid specified (i.e., UUA → UUG, both specifying leucine). (Contrast with nonsynonymous substitution, missense mutation, nonsense mutation.)

systematics The scientific study of the diversity and relationships among organisms.

systemic acquired resistance A general resistance to many plant pathogens following infection by a single agent.

systemic circuit Portion of the circulatory system by which oxygenated blood from the lungs or gills is distributed throughout the rest of the body and returned to the heart. (Contrast with pulmonary circuit.)

systems biology The scientific study of an organism as an integrated and interacting system of genes, proteins, and biochemical reactions.

systole (sis' tuh lee) [Gk.: contraction] Contraction of a chamber of the heart, driving blood forward in the circulatory system. (Contrast with diastole.)

T

3' end (3 prime) The end of a DNA or RNA strand that has a free hydroxyl group at the 3' carbon of the sugar (deoxyribose or ribose).

T cell A type of lymphocyte involved in the cellular immune response. The final stages of its development occur in the thymus gland. (Contrast with B cell; see also cytotoxic T cell, T-helper cell.)

T cell receptor A protein on the surface of a T cell that recognizes the antigenic determinant for which the cell is specific.

T tubules A system of tubules that runs throughout the cytoplasm of a muscle fiber, through which action potentials spread.

T-helper (T_H) cell Type of T cell that stimulates events in both the cellular and humoral immune responses by binding to the antigen on an antigen-presenting cell; target of the HIV-I virus, the agent of AIDS. (Contrast with cytotoxic T cells.)

taproot system A root system typical of eudicots consisting of a primary root (*taproot*) that extends downward by tip growth and outward by initiating lateral roots. (Contrast with fibrous root system.)

target cell A cell with the appropriate receptors to bind and respond to a particular hormone or other chemical mediator.

taste bud A structure in the epithelium of the tongue that includes a cluster of chemoreceptors innervated by sensory neurons.

TATA box An eight-base-pair sequence, found about 25 base pairs before the starting point for transcription in many eukaryotic promoters, that binds a transcription factor and thus helps initiate transcription.

taxon (plural: taxa) [Gk. *taxis*: put in order] A biological group (typically a species or a clade) that is given a name.

T_C cells See cytotoxic T cells.

tectonic membrane One of two membranes (the other is the basilar membrane) that extend along the length of the cochlea in the human ear. Also known as Reissner's membrane.

telencephalon The outer, surrounding structure of the embryonic vertebrate forebrain, which develops into the cerebrum.

telomerase An enzyme that catalyzes the addition of telomeric sequences lost from chromosomes during DNA replication.

telomeres (tee' lo merz) [Gk. *telos*: end + *meros*: units, segments] Repeated DNA sequences at the ends of eukaryotic chromosomes.

telophase (tee' lo phase) [Gk. *telos*: end] The final phase of mitosis or meiosis during which chromosomes become diffuse, nuclear envelopes re-form, and nucleoli begin to reappear in the daughter nuclei.

template A molecule or surface on which another molecule is synthesized in complementary fashion, as in the replication of DNA.

template strand In double-stranded DNA, the strand that is transcribed to create an RNA transcript that will be processed into a protein. Also refers to a strand of RNA that is used to create a complementary RNA.

temporal lobe One of the four lobes of the cerebral hemisphere; receives and processes auditory and visual information; involved in recognizing, identifying, and naming objects.

temporal summation In the production or inhibition of action potentials in a postsynaptic cell, the interaction of depolarizations or hyperpolarizations produced by rapidly repeated stimulation of a single point on the postsynaptic cell. (Contrast with spatial summation.)

tendon A collagen-containing band of tissue that connects a muscle with a bone.

tepál A sterile, modified, nonphotosynthetic leaf of an angiosperm flower that cannot be distinguished as a petal or a sepal.

termination In molecular biology, the end of transcription or translation.

terminator A sequence at the 3' end of mRNA that causes the RNA strand to be released from the transcription complex.

terrestrial (ter res' tree all) [L. *terra*: earth] Pertaining to or living on land. (Contrast with aquatic, marine.)

territorial behavior Aggressive actions engaged in to defend a habitat or resource such that other animals are denied access.

tertiary consumers Carnivores that consume primary carnivores (secondary consumers).

tertiary endosymbiosis The mechanism by which some eukaryotes acquired the capacity for photosynthesis; for example, a dinoflagellate that apparently lost its chloroplast became photosynthetic by engulfing another protist that had acquired a chloroplast through secondary endosymbiosis.

tertiary structure In reference to a protein, the relative locations in three-dimensional space of all the atoms in the molecule. The overall shape of a protein. (Contrast with primary, secondary, and quaternary structures.)

test cross Mating of a dominant-phenotype individual (who may be either heterozygous or homozygous) with a homozygous-recessive individual.

testis (tes' tis) (plural: testes) [L. *testis*: witness] The male gonad; the organ that produces the male gametes.

tetanus [Gk. *tetanos*: stretched] (1) A state of sustained maximal muscular contraction caused by rapidly repeated stimulation. (2) In medicine, an often fatal disease ("lockjaw") caused by the bacterium *Clostridium tetani*.

tetrad [Gk. *tettares*: four] During prophase I of meiosis, the association of a pair of homologous chromosomes or four chromatids

thalamus [Gk. *thalamos*: chamber] A region of the vertebrate forebrain; involved in integration of sensory input.

theory [Gk. *theoria*: analysis of facts] A far-reaching explanation of observed facts that is supported by such a wide body of evidence, with no significant contradictory evidence, that it is scientifically accepted as a factual framework. Examples are Newton's theory of gravity and Darwin's theory of evolution. (Contrast with hypothesis.)

thermoneutral zone (TNZ) [Gk. *thermos*: temperature] The range of temperatures over which an endotherm does not have to expend extra energy to thermoregulate.

thermophile (ther' muh fyle) [Gk. *thermos*: temperature + *philos*: loving] An organism that lives exclusively in hot environments.

thoracic cavity [Gk. *thorax*: breastplate] The portion of the mammalian body cavity bounded by the ribs, shoulders, and diaphragm. Contains the heart and the lungs.

thoracic duct The connection between the lymphatic system and the circulatory system.

threshold The level of depolarization that causes an electrically excitable membrane to fire an action potential.

thrombin An enzyme involved in blood clotting; cleaves fibrinogen to form fibrin.

thrombus (throm' bus) [Gk. *thrombos*: clot] A blood clot that forms within a blood vessel and remains attached to the wall of the vessel.

thylakoid (thigh' la koid) [Gk. *thylakos*: sack or pouch] A flattened sac within a chloroplast. Thylakoid membranes contain all of the chlorophyll in a plant, in addition to the electron carriers of photophosphorylation. Thylakoids stack to form grana.

thymine (T) Nitrogen-containing base found in DNA.

thymus [Gk. *thymos*: warty] A ductless, glandular lymphoid tissue, involved in development of the immune system of vertebrates. In humans, the thymus degenerates during puberty.

thyroid gland [Gk. *thyreos*: door-shaped] A two-lobed gland in vertebrates. Produces the hormone thyroxine.

thyrotropin Hormone produced by the anterior pituitary that stimulates the thyroid gland to produce and release thyroxine. Also called thyroid-stimulating hormone (TSH).

thyrotropin-releasing hormone (TRH) Hormone produced by the hypothalamus that stimulates the anterior pituitary to release thyrotropin.

thyroxine Hormone produced by the thyroid gland; controls many metabolic processes.

tidal The bidirectional form of ventilation used by all vertebrates except birds; air enters and leaves the lungs by the same route.

tight junction A junction between epithelial cells in which there is no gap between adjacent cells.

tissue A group of similar cells organized into a functional unit; usually integrated with other tissues to form part of an organ.

tissue system In plants, any of three organized groups of tissues—dermal tissue, vascular tissue, and ground tissue—that are established during embryogenesis and have distinct functions.

titin A protein that holds bundles of myosin filaments in a centered position within the sarcomeres of muscle cells. The largest protein in the human body.

tonoplast The membrane of the plant central vacuole.

topsoil The uppermost soil horizon; contains most of the organic matter of soil, but may be depleted of most mineral nutrients by leaching. Also called the A horizon.

totipotent [L. *toto*: whole, entire + *potens*: powerful] Possessing all the genetic information and other capacities necessary to form an entire individual. (Contrast with multipotent, pluripotent.)

toxigenicity The ability of some pathogenic bacteria to produce chemical substances that harm the host.

trachea (tray' kee ah) [Gk. *trakhoia*: tube] A tube that carries air to the bronchi of the lungs of vertebrates. When plural (*tracheae*), refers to the major airways of insects.

tracheary element Either of two types of xylem cells—tracheids and vessel elements—that undergo apoptosis before assuming their transport function.

tracheid (tray' kee id) A type of tracheary element found in the xylem of nearly all vascular plants, characterized by tapering ends and walls that are pitted but not perforated. (Contrast with vessel element.)

trade-off The relationship between the fitness benefits conferred by an adaptation and the fitness costs it imposes. For an adaptation to be favored by natural selection, the benefits must exceed the costs.

trait In genetics, a specific form of a character: eye color is a character; brown eyes and blue eyes are traits. (Contrast with character.)

transcription The synthesis of RNA using one strand of DNA as a template.

transcription factors Proteins that assemble on a eukaryotic chromosome, allowing RNA polymerase II to perform transcription.

transcription initiation site The part of a gene's promoter where synthesis of the gene's RNA transcript begins.

transduction (1) Transfer of genes from one bacterium to another by a bacteriophage. (2) In sensory cells, the transformation of a stimulus (e.g., light energy, sound pressure waves, chemical or electrical stimulants) into action potentials.

transfection Insertion of recombinant DNA into animal cells.

transfer RNA (tRNA) A family of folded RNA molecules. Each tRNA carries a specific amino acid and anticodon that will pair with the complementary codon in mRNA during translation.

transformation (1) A mechanism for transfer of genetic information in bacteria in which pure DNA from a bacterium of one genotype is taken in through the cell surface of a bacterium of a different genotype and incorporated into the chromosome of the recipient cell. (2) Insertion of recombinant DNA into a host cell.

transgenic Containing recombinant DNA incorporated into the genetic material.

transition state In an enzyme-catalyzed reaction, the reactive condition of the substrate after there has been sufficient input of energy (activation energy) to initiate the reaction.

translation The synthesis of a protein (polypeptide). Takes place on ribosomes, using the information encoded in messenger RNA.

translational repressor A protein that blocks translation by binding to mRNAs and preventing their attachment to the ribosome. In mammals, the production of ferritin protein is regulated by a translational repressor.

translocation (1) In genetics, a rare mutational event that moves a portion of a

chromosome to a new location, generally on a nonhomologous chromosome. (2) In vascular plants, movement of solutes in the phloem.

transmembrane protein An integral membrane protein that spans the phospholipid bilayer.

transpiration [L. *spirare*: to breathe] The evaporation of water from plant leaves and stem, driven by heat from the sun, and providing the motive force to raise water (plus mineral nutrients) from the roots.

transpiration-cohesion-tension mechanism Theoretical basis for water movement in plants: evaporation of water from cells within leaves (transpiration) causes an increase in surface tension, pulling water up through the xylem. Cohesion of water occurs because of hydrogen bonding.

transposable element (transposon) A segment of DNA that can move to, or give rise to copies at, another locus on the same or a different chromosome.

transversion A mutation that changes a purine to a pyrimidine or vice versa.

tree of life A term that encompasses the evolutionary history of all life, or a graphic representation of that history.

triglyceride A simple lipid in which three fatty acids are combined with one molecule of glycerol.

trimesters The three stages of human pregnancy, approximately 3 months each in length.

tripartite synapse The idea that a synapse includes not only the pre- and postsynaptic neurons involved but also encompasses many connections with glial cells called astrocytes.

triploblastic Having three cell layers.

trisomic Containing three rather than two members of a chromosome pair.

tRNA See transfer RNA.

trochophore (trok' o fore) [Gk. *trochos*: wheel + *phoreus*: bearer] A radially symmetrical larval form typical of annelids and mollusks, distinguished by a wheel-like band of cilia around the middle.

trophic cascade The progression over successively lower trophic levels of the indirect effects of a predator.

trophic interactions The consumer-resource relationships among species in a community.

trophic level [Gk *trophes*: nourishment] A group of organisms united by obtaining their energy from the same part of the food web of a biological community.

trophoblast [Gk *trophes*: nourishment + *blastos*: sprout] At the 32-cell stage of mammalian development, the outer group of cells that will become part of the placenta and thus nourish the growing embryo. (Contrast with inner cell mass.)

tropic hormones Hormones produced by the anterior pituitary that control the secretion of hormones by other endocrine glands.

tropomyosin [troe poh my' oh sin] One of the three protein components of an actin filament; controls the interactions of actin and myosin necessary for muscle contraction.

tropoin One of the three components of an actin filament; binds to actin, tropomyosin, and Ca^{2+} .

true-breeding A genetic cross in which the same result occurs every time with respect to the trait(s) under consideration, due to homozygous parents.

trypsin A protein-digesting enzyme. Secreted by the pancreas in its inactive form (trypsinogen), it becomes active in the duodenum of the small intestine.

tube feet A unique feature of echinoderms; extensions of the water vascular system, which functions in gas exchange, locomotion, and feeding.

tubulin A protein that polymerizes to form microtubules.

tumor [L. *tumor*: a swollen mass] A disorganized mass of cells. Malignant tumors spread to other parts of the body.

tumor necrosis factor A family of cytokines (growth factors) that causes cell death and is involved in inflammation.

tumor suppressor A gene that codes for a protein product that inhibits cell proliferation; inactive in cancer cells. (Contrast with oncogene.)

turgor pressure [L. *turgidus*: swollen] See pressure potential.

turnover In freshwater ecosystems, vertical movements of water that bring nutrients and dissolved CO_2 to the surface and O_2 to deeper water.

twitch A muscle fiber's minimum unit of contraction, stimulated by a single action potential.

tympanic membrane [Gk. *tympanum*: drum] The eardrum.

U

ubiquitin A small protein that is covalently linked to other cellular proteins identified for breakdown by the proteasome.

ultimate causes In ethology, the evolutionary processes that produce an animal's capacity and tendency to behave in particular ways. (Contrast with proximate causes.)

unequal crossing over When a highly repeated gene sequence becomes displaced in alignment during meiotic crossing over, so that one chromosome receives many copies of the sequence while the second chromosome receives fewer copies. One of the mechanisms of concerted evolution. (See also biased gene conversion.)

uniporter [L. *unus*: one + *portal*: doorway] A membrane transport protein that carries a single substance in one direction. (Contrast with antiporter, symporter.)

unipotent An undifferentiated cell that is capable of becoming only one type of mature

cell. (Contrast with totipotent, multipotent, pluripotent.)

unsaturated fatty acid A fatty acid whose hydrocarbon chain contains one or more double bonds. (Contrast with saturated fatty acid.)

upregulation A process by which the abundance of receptors for a hormone increases when hormone secretion is suppressed. (Contrast with downregulation.)

upwelling zones Areas of the ocean where cool, nutrient-rich water from deeper layers rises to the surface.

uracil (U) A pyrimidine base found in nucleotides of RNA.

urea A compound that is the main form of nitrogen excreted by many animals, including mammals.

ureotelic Pertaining to an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is urea. (Contrast with ammonotelic, uricotelic.)

ureter (your' uh tur) Long duct leading from the vertebrate kidney to the urinary bladder or the cloaca.

urethra (you ree' thra) In most mammals, the canal through which urine is discharged from the bladder and which serves as the genital duct in males.

uric acid A compound that serves as the main excreted form of nitrogen in some animals, particularly those which must conserve water, such as birds, insects, and reptiles.

uricotelic Pertaining to an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is uric acid. (Contrast with ammonotelic, ureotelic.)

urinary bladder A structure in which urine is stored until it can be excreted to the outside of the body.

urine (you' rin) In vertebrates, the fluid waste product containing the toxic nitrogenous by-products of protein and nucleic acid metabolism.

uterine cycle In human females, the monthly cycle of events by which the endometrium is prepared for the arrival of a blastocyst. (Contrast with ovarian cycle.)

uterus (yoo' ter us) [L. *utero*: womb] A specialized portion of the female reproductive tract in mammals that receives the fertilized egg and nurtures the embryo in its early development. Also called the womb.

V

vaccination Injection of virus or bacteria or their proteins into the body, to induce immunity. The injected material is usually attenuated (weakened) before injection and is called a *vaccine*.

vacuole (vac' yew ole) Membrane-enclosed organelle in plant cells that can function for storage, water concentration for turgor, or hydrolysis of stored macromolecules.

vagina (vuh jine' uh) [L. *sheath*] In female animals, the entry to the reproductive tract.

van der Waals forces Weak attractions between atoms resulting from the interaction of the electrons of one atom with the nucleus of another. This type of attraction is about one-fourth as strong as a hydrogen bond.

variable In a controlled experiment, a factor that is manipulated to test its effect on a phenomenon.

variable region The portion of an immunoglobulin molecule or T cell receptor that includes the antigen-binding site and is responsible for its specificity. (Contrast with constant region.)

vas deferens (plural: vasa deferentia) Duct that transfers sperm from the epididymis to the urethra.

vasa recta Blood vessels that parallel the loops of Henle and the collecting ducts in the renal medulla of the kidney.

vascular (vas' kew lar) [L. *vasculum*: a small vessel] Pertaining to organs and tissues that conduct fluid, such as blood vessels in animals and xylem and phloem in plants.

vascular bundle In vascular plants, a strand of vascular tissue, including xylem and phloem as well as thick-walled fibers.

vascular cambium (kam' bee um) [L. *cambiare*: to exchange] In plants, a lateral meristem that gives rise to secondary xylem and phloem.

vascular tissue system The transport system of a vascular plant, consisting primarily of xylem and phloem.

vasopressin A hormone that promotes water reabsorption by the kidney. Produced by neurons in the hypothalamus and released from nerve terminals in the posterior pituitary. Also called antidiuretic hormone or ADH.

vector (1) An agent, such as an insect, that carries a pathogen affecting another species. (2) A plasmid or virus that carries an inserted piece of DNA into a bacterium for cloning purposes in recombinant DNA technology.

vegetal hemisphere The lower portion of some animal eggs, zygotes, and embryos, in which the dense nutrient yolk settles. The *vegetal pole* is to the very bottom of the egg or embryo. (Contrast with animal hemisphere.)

vegetative Nonreproductive, nonflowering, or asexual.

vegetative meristem An apical meristem that produces leaves.

vegetative reproduction Asexual reproduction through the modification of stems, leaves, or roots.

vein [L. *vena*: channel] A blood vessel that returns blood to the heart. (Contrast with artery.)

vena cavae In the circulatory systems of crocodilians, birds, and mammals, large veins that empty into the right atrium of the heart.

ventral [L. *venter*: belly, womb] Toward or pertaining to the belly or lower side. (Contrast with dorsal.)

ventricle A muscular heart chamber that pumps blood through the lungs or through the body.

venule A small blood vessel draining a capillary bed that joins others of its kind to form a vein. (Contrast with arteriole.)

vernalization [L. *vernalis*: spring] Events occurring during a required chilling period, leading eventually to flowering.

vertebral column [L. *vertebra*: to turn] The jointed, dorsal column that is the primary support structure of vertebrates.

very low-density lipoproteins (VLDLs) Lipoproteins that consist mainly of triglyceride fats, which they transport to fat cells in adipose tissues throughout the body; associated with excessive fat deposition and high risk for cardiovascular disease.

vesicle Within the cytoplasm, a membrane-enclosed compartment that is associated with other organelles; the Golgi complex is one example.

vessel element A type of tracheary element with perforated end walls; found only in angiosperms. (Contrast with tracheid.)

vestibular system (ves tib' yew lar) [L. *vestibulum*: an enclosed passage] Structures within the inner ear that sense changes in position or momentum of the head, affecting balance and motor skills.

vicariant event (vye care' ee unt) [L. *vicus*: change] The splitting of a taxon's range by the imposition of some barrier to dispersal.

villus (vil' lus) (plural: villi) [L. *villus*: shaggy hair or beard] A hairlike projection from a membrane; for example, from many gut walls.

virion (veer' e on) The virus particle, the minimum unit capable of infecting a cell.

virulence [L. *virus*: poison, slimy liquid] The ability of a pathogen to cause disease and death.

virus Any of a group of ultramicroscopic particles constructed of nucleic acid and protein (and, sometimes, lipid) that require living cells in order to reproduce. Viruses evolved multiple times from different cellular species.

vital capacity (VC) The maximum capacity for air exchange in one breath; the sum of the tidal volume and the inspiratory and expiratory reserve volumes.

vitamin [L. *vita*: life] An organic compound that an organism cannot synthesize, but nevertheless requires in small quantities for normal growth and metabolism.

vitelline envelope The inner, proteinaceous protective layer of a sea urchin egg.

viviparity (vye vi par' uh tee) Reproduction in which fertilization of the egg and development of the embryo occur inside the mother's body. (Contrast with oviparity.)

vivipary Premature germination in plants.

voltage A measure of the difference in electrical charge between two points.

voltage-gated channel A type of gated channel that opens or closes when a certain voltage exists across the membrane in which it is inserted.

vomerolateral organ (VNO) Chemosensory structure embedded in the nasal epithelium of amphibians, reptiles, and many mammals. Often specialized for detecting pheromones.

W

warning coloration See aposematism

water potential (ψ , Ψ) In osmosis, the tendency for a system (a cell or solution) to take up water from pure water through a differentially permeable membrane. Water flows toward the system with a more negative water potential. (Contrast with solute potential, pressure potential.)

water vascular system In echinoderms, a network of water-filled canals that functions in gas exchange, locomotion, and feeding.

wavelength The distance between successive peaks of a wave train, such as electromagnetic radiation.

weather The state of atmospheric conditions in a particular place at a particular time. (Contrast with climate.)

weathering The mechanical and chemical processes by which rocks are broken down into soil particles.

Wernicke's area A region in the temporal lobe of the human brain that is involved with the sensory aspects of language.

white blood cells Cells in the blood plasma that play defensive roles in the immune system. Also called leukocytes.

white matter In the central nervous system, tissue that is rich in axons. (Contrast with gray matter.)

wild type Geneticists' term for standard or reference type. Deviants from this standard,

even if the deviants are found in the wild, are usually referred to as mutant. (Note that this terminology is not usually applied to human genes.)

wood Secondary xylem tissue.

X-Y-Z

xerophyte (zee' row fyte) [Gk. *xerox*: dry + *phyton*: plant] A plant adapted to an environment with limited water supply.

xylem (zy' lum) [Gk. *xylon*: wood] In vascular plants, the tissue that conducts water and minerals; xylem consists, in various plants, of tracheids, vessel elements, fibers, and other highly specialized cells.

yolk [M.E. *yolke*: yellow] The stored food material in animal eggs, rich in protein and lipids.

yolk sac In reptiles, birds, and mammals, the extraembryonic membrane that forms from the endoderm of the hypoblast; it encloses and digests the yolk.

zeaxanthin A blue-light receptor involved in the opening of plant stomata.

zona pellucida A jellylike substance that surrounds the mammalian ovum when it is released from the ovary.

zone of cell division The apical and primary meristems of a plant root; the source of all cells of the root's primary tissues.

zone of cell elongation The part of a plant root, generally above the zone of cell division, where cells are expanding (growing), primarily in the longitudinal direction.

zone of maturation The part of a plant root, generally above the zone of cell elongation, where cells are differentiating.

zoospore (zoe' o spore) [Gk. *zoon*: animal + *spora*: seed] In algae and fungi, any swimming spore. May be diploid or haploid.

zygospore Multinucleate, diploid cell that is a resting stage in the life cycle of zygosporic fungi.

zygote (zye' gote) [Gk. *zygotos*: yoked] The cell created by the union of two gametes, in which the gamete nuclei are also fused. The earliest stage of the diploid generation.

zymogen The inactive precursor of a digestive enzyme; secreted into the lumen of the gut, where a protease cleaves it to form the active enzyme.

 overview, 393
 primary and secondary growth defined, 715
 primary indeterminate growth, 715–720
 processes in, 710
 properties affecting, 710–711
 role of auxin in, 762–767
 secondary growth, 721–723
 seed germination and seedling growth, 757–758
 Plant growth regulation
 auxin and, 762–767
 brassinosteroids and, 771
 cytokinins and, 768–769
 ethylene and, 769–771
 genetic screens and the identification of signal transduction pathways, 759, 760
 gibberellins and, 760–762
 hormones and photoreceptors in, 758–759, 771–775
 key factors in, 757
 Plant hormones
 auxins, 760, 762–767
 brassinosteroids, 771
 compared to animal hormones, 758
 cytokinins, 768–769
 ethylene, 769–771
 gibberellins, 760–762, 767
 in plant defenses against herbivory, 804, 805
 in plant growth and development, 758–759
 production in response to pathogens, 799
 structures of, 759
 “Plant immune system,” 799–801
 “Plant kingdom,” 573
 Plant mutualisms
 food exchange for housing or defense, 1178–1179

- food exchange for seed transport, 1181–1182
pollination syndromes, 1180–1181
See also Mycorrhizae
- Plant nutrition**
carnivorous plants, 751–752
deficiency symptoms, 742
essential macronutrients and micronutrients, 741–743
hydroponic experiments, 742–743
impact of soil on nutrient availability, 744–747
improving nitrogen use efficiency, 740
influence of fungi and bacteria on root uptake of nutrients, 747–751
parasitic plants, 752–753
plant acquisition of nutrients, 743–744
plant regulation of nutrient uptake and assimilation, 744
- Plant pathogens**
plant defenses against, 798–801
plant–pathogen signaling, 799
- Plant physiology, 708**
- Plant reproduction**
asexual reproduction in angiosperms, 792–794
sexual reproduction in angiosperms, 779–785
- Plant signal transduction pathways**
activation in response to pathogens, 799, 800
ethylene pathway, 770–771
involving auxins and gibberellins, 767
involving cytokinins, 768–769
in plant defenses against herbivory, 804, 805
- Plant tissue culture, 768**
- Plant tissue systems**
dermal tissue, 712–713
ground tissue, 712, 713–714
primary meristems in the origin of, 716
vascular tissue, 712, 714–715
- Plantae, 570–571**
- Plantlets, 793**
- Plant–pollinator relationship**
coevolution in, 588, 598–599, 605
pollination syndromes, 1180–1181
- Plants**
adaptations (*see* Adaptations in plants)
aerenchyma, 808
agricultural applications of biotechnology, 386–388, 389
aspects of light responsive to, 771
“bolting,” 761
carnivorous, 751–752
challenges of saline environments, 810–811
cloning, 405–406
colonization of the land, 574–579
cuticle, 732
cytoplasmic inheritance, 252
development in (*see* Plant growth and development)
effect of pollination strategies on speciation rates, 480
effects of domestication on, 723–724
endophytic fungi and, 615
entrainment of circadian rhythms, 774–775
environmental stresses on, 806
evolution of, 570
evolution of photosynthesis in, 570–573
global nitrogen cycle, 750–751
heavy metal tolerance, 811–812
hypersensitive response, 226
impact of soil structure on, 744–747
improving nitrogen use efficiency, 740
interactions with the external environment, 9
lateral gene transfer, 496
metabolic interactions involving photosynthesis, 200–202
metabolomes, 370
morphogenesis, 710–712
mycorrhizae and, 614–615
nitrogen composition, 751
nutrients and nutrition (*see* Plant nutrition)
optimal soil pH, 746
organ identity genes, 400–401
parasitic, 752–753
partial reproductive isolation in, 470–471
photomorphogenesis, 772
photosynthetic efficiency, 201–202
phytomining, 812
phytoremediation, 811, 812
plastid gene mutations, 252
plastid structure and function, 92–93
polyploidy and agriculture, 225, 226
postzygotic isolating mechanisms, 478, 479
prezygotic isolating mechanisms, 476, 477
reciprocal interactions with herbivores, 1175–1176
responses to drought and water stress, 734, 809
root and shoot systems, 709
self-incompatibility studies, 380–381
self-protection from chemical defenses, 805
starches and starch grains, 53
stem cells, 408
stomatal control of water loss and carbon dioxide uptake, 732–734
stress response, 337
sympatric speciation through polyploidy, 475
translocation in phloem, 734–738
transport systems for ions, 744
triglycerides of, 57
uptake of water and solutes, 727–730
water-use efficiency, 726
waxes, 59
xylem transport of water and minerals, 730–732
See also Angiosperms; Crop plants; Gymnosperms; Land plants; Nonvascular land plants; Seed plants; Vascular plants
